Feeds & Feeding :- A Hand book
for the student and stockman

by

Morrison, Frank B.

starch and is therefore often called "animal starch." Normally, from 3 to 7 per cent of the weight of the liver is glycogen. Some glycogen is also formed in the other tissues of the body, especially the muscles. The glycogen in the muscles is used in the production of muscular work, as is described in Chapter X.

The glucose in the general blood circulation is continuously removed to nourish the various body tissues. To replenish the supply of glucose in the blood the glycogen is gradually changed back to glucose. This is then given out to the blood, as needed to keep the glucose content approximately constant. (The blood of cattle and sheep normally has 0.30 to 0.70 parts of glucose per 1,000 parts. That of swine and horses may be higher, and that of poultry has twice as much or more.[5])

44. Digestion of cellulose and pentosans.—No enzymes produced by the digestive tract are able to digest cellulose and pentosans, which form the cell walls of plants and make up a large part of all roughages. However, these substances are attacked by bacteria in the first three compartments of the stomach of ruminants, in the caecum and colon of the horse, and to a lesser extent in the large intestine of other animals. The number of bacteria in the rumen contents is tremendous. Each ounce of the contents may have trillions of bacteria.

These bacteria break down the cellulose and pentosans into organic acids (chiefly acetic acid) and possibly to a small extent into simple sugars. In this process gases (principally carbon dioxide and methane) are formed and heat is produced.

The organic acids serve as food to the animal, the same as sugars, but the gases are of no value. The heat produced is an entire waste, unless the animal needs this heat to maintain its normal body temperature. Recent studies show that some absorption of soluble nutrients, such as organic acids, can take place from the stomach of ruminants, but most of the absorption is from the small intestine.

The ability of livestock to use the fiber and pentosans in their feeds depends on this bacterial digestion. It is therefore of great importance in the nutrition of cattle and sheep, and is the fundamental reason why they can live chiefly on roughage. Not only are the fibrous cell walls thus utilized for food, but also this digestion sets free the nutrients contained inside the cells, so they can be more easily acted on by the digestive juices in the true stomach and in the intestines. The lignin in feeds is digested only to a very small extent. (**11**)

Some digestion of protein into simpler compounds occurs in the bacterial action, the bacteria building the simpler compounds into protein in the bacterial cells. The bacteria are also able to use simple forms of nitrogen compounds, such as urea, in their growth, building them into protein. (**128**) Also, starch-like complex carbohydrates may be formed in some of the bacterial cells.

The bacteria and other microorganisms are mostly digested in the true stomach (abomasum) and the small intestine, thus furnishing nutrients to the ruminant animal. In this manner a ruminant can use such a simple nitrogenous compound as urea to replace part of the protein in its food. (**112**)

Investigations have shown that all of the B-complex vitamins are formed by the rumen bacteria in their growth and become available to the ruminant through the digestion of the bacteria. (**208**) Therefore the ruminant may need no B-complex vitamins in its food.

Not only do the bacteria digest cellulose and pentosans, but also they may attack starch and sugar. This action is detrimental, for these nutrients would be digested more efficiently later on in the small intestine, while in the bacterial digestion an appreciable part of their feeding value is lost through the heat and gases produced in the fermentations.

The fact that practically no ptyalin is present in the saliva of cattle and sheep is advantageous to them. If their saliva converted starch into sugar, much sugar would be formed in the rumen.

44

This would then be attacked by bacteria, with a resultant loss of nutrients.

In addition to the digestion in the rumen caused by bacteria, more or less digestion is undoubtedly produced by the enzymes contained in some foods, such as the cereal grains, for the moisture and warmth of the rumen are favorable to enzyme action in general. Also, certain protozoa (microorganisms larger in size than bacteria) thrive in the food mass in the rumen and apparently aid in the digestive processes.

Ruminants get rid of most of the gas produced in the fermentations through belching, though some is absorbed into the blood and escapes by way of the lungs. Sometimes this belching process does not occur normally, and bloat results, as is described later. (49)

45. Studies on digestion in rumen.—Recently many scientists have conducted studies on the various factors that affect the efficiency of digestion in the rumen.[6] Some of the experiments have been with a so-called "artificial rumen," in which digestion occurs similar to that in the rumen of an animal. Other studies have been with animals operated on to make a permanent opening, or fistula, into the rumen. In still other experiments, the effects of various feeds or food additions have been determined in digestion trials with normal ruminants.

These investigations have shown that the rumen bacteria have very specific nutrient needs for their maximum development, just as the host animal itself has definite nutrient requirements. A deficiency in the rumen contents of a nutrient which the bacteria need will decidedly decrease the bacterial growth and therefore lessen the digestion in the rumen.

For example, a lack of protein or of a substitute simpler form of nitrogen, such as urea, will decrease digestion of cellulose. Similarly, digestion will be impaired by a lack of essential minerals, including the trace minerals. As shown later, the chief need for cobalt by ruminants may be to make possible normal development of the rumen bacteria. (175)

In experiments with the artificial rumen in which a purified culture solution has been used, containing presumably adequate supplies of protein and minerals, the digestion of cellulose has been increased by the addition of several substances. These include rumen liquid from a normal animal, grass juice, alfalfa hay or alfalfa ash, valeric acid and certain other fatty acids, and partly digested protein. The nutrient requirements of the rumen bacteria therefore seem complex. Fortunately, their needs are readily met when ruminants are fed ordinary well-balanced rations that include good roughage.

The experiments have shown that for satisfactory digestion of poor roughage, such as ground corn cobs, straw, cottonseed hulls, or even very poor late-cut hay, adequate supplementation is needed with protein or another source of nitrogen, and with minerals, including perhaps trace minerals. The addition to such roughage of a small amount of high-quality roughage, such as good alfalfa hay, will generally increase rumen digestion greatly, through furnishing needed protein, trace minerals, or some unknown factor needed in the bacterial growth.

On the other hand, when there is an adequate proportion of good roughage in a properly balanced ration, no special supplementation is required to ensure efficient digestion.

At birth, the rumen is developed but little, and there are few fiber-digesting bacteria. A very young calf can therefore make but little use of hay or other roughage until its rumen develops. Opinions differ as to whether there is generally any benefit from inoculating young dairy calves with cuds from mature cattle. (1123) Sometimes veterinarians use the transfer of rumen contents from a normal animal in treating cases of severe indigestion in cattle.

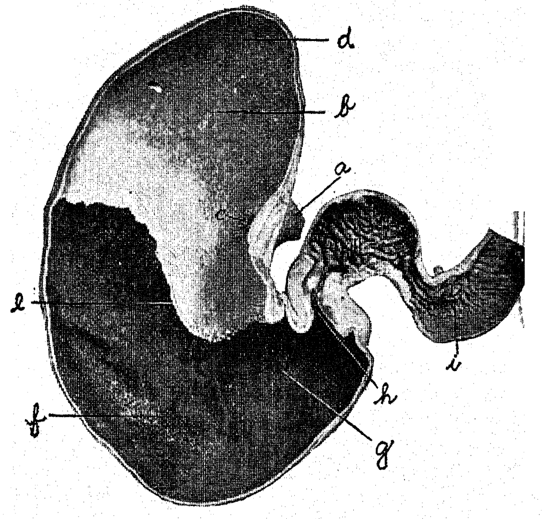
46. Digestion and absorption of protein.—The proteins of the food are first attacked in the stomach by pepsin, an enzyme of the gastric juice, which splits them into proteoses and peptones. These are soluble and simpler in com-

position than the proteins, but are still very complex in structure.

The proteoses and peptones, together with any protein that escapes action by pepsin, pass into the small intestine. There trypsin, an enzyme in the pancreatic juice, not only cleaves the undigested protein into proteoses and peptones, but also digests the proteoses and peptones further, splitting them into amino acids, which are much simpler. Through the action of trypsin and of

In the case of suckling animals or others consuming milk, rennin, which is an enzyme in the gastric juice, is of importance. This curdles milk, changing it from a liquid to a solid, so that it cannot pass too rapidly through the stomach and thus escape digestion.

47. Digestion and absorption of fats.—The fats of foods undergo no appreciable digestion until they reach the small intestine. Here, through the aid of the bile produced by the liver, the fat



LONGITUDINAL SECTION OF STOMACH OF THE HORSE

(From Sisson, "Anatomy of the Domestic Animals.")

other enzymes in the pancreatic juice and the intestinal juice, practically all the protein that can be digested is broken down into amino acids. A little may be left in the form of peptides, which are relatively simple combinations of two or more amino acids.

The amino acids are soluble and are readily absorbed by the villi of the walls of the small intestine. They then pass into the blood and are carried to nourish all parts of the body. Small amounts of peptides may be absorbed in the same manner.

is emulsified, or broken up into very small droplets. Lipase, an enzyme in the pancreatic juice, which is activated by bile, then splits the fats into fatty acids and glycerol. These are absorbed by the villi of the intestine. It is possible that some unchanged fat may also be absorbed in emulsified form. In addition, small amounts of the fatty acids may unite with the alkalies in the digestive fluids to form soaps, which are readily absorbed.

In the villi the fatty acids are reunited with glycerol to form fat. The fat

is then carried chiefly in the lymph system to a vein near the heart, where it enters the blood circulation. (It is the opinion of some that in the process of absorption the fatty acids are converted into phospholipids, which are mostly changed to fat in the intestinal walls.) (14)

48. Minerals; vitamins; water.—The mineral matter in feeds that is not already soluble is dissolved to a greater or less extent by the hydrochloric acid in the gastic juice of the stomach. Further freeing of mineral nutrients occurs as the organic nutrients are digested by the several enzymes. Minerals are absorbed chiefly from the small intestine.

Little is known about the manner in which the vitamins are digested and absorbed.

Water requires no digestion, and it is absorbed along the digestive tract, chiefly in the small intestine.

49. Bloat.—Many studies have been carried on in an endeavor to determine the exact causes of bloat in ruminants and to find methods of preventing it.[7] However, many problems concerning bloat are still only partly solved.

Bloat results when the gases produced in the fermentations occurring in the rumen do not escape normally, but accumulate, causing great distension of the rumen. In severe bloat, death frequently results, and even when the animal does not die, production may be seriously reduced.

Cattle are somewhat more apt to suffer from bloat than sheep, and animals consuming a large amount of feed are more likely to bloat than those eating less. For this reason dairy cows in milk are more subject to bloat than dry cows or heifers, and ewes nursing lambs bloat more frequently than other sheep.

Legume pasture of certain kinds, especially before bloom, is most likely to cause bloat. Alfalfa and Ladino clover seem to cause more trouble than red, alsike, or sweet clover. Birdsfoot trefoil apparently does not cause bloat. Bloat rarely occurs on grass pasture, and there is usually little trouble on mixed legume-grass pasture if grass forms at least half of the forage and if the stand of grass is even and uniform throughout the pasture.

Pasturing a legume only after it has reached the blooming stage helps prevent the trouble. Bloat seems to be apt to occur when the growth of the legume has been very rapid during a period of warm, rainy weather.

If both stems and leaves of green alfalfa are eaten, bloat may not occur, while cattle grazing selectively and eating only the tops and leaves have trouble.

Although there is unfortunately trouble from bloat on pastures containing a large proportion of such legumes as alfalfa and Ladino clover, the greater yield and higher feeding value of these pastures more than offset this disadvantage, if due care is taken to prevent bloat.

It was previously thought that bloat was caused by an unusually rapid production of gas in the rumen, as a result of eating a large amount of lush, readily-fermentable green forage. Recent studies indicate, however, that bloat-producing feeds do not necessarily produce more gas. Bloat is caused by a failure to get rid of the gas rapidly enough. Some of the gas normally produced in the rumen is absorbed into the blood and escapes by way of the lungs, but most of it is expelled by belching.

Many cases of bloat are "frothy bloat," in which the gas is in very small bubbles, which are entrapped in the rumen contents. Much of the gas can then not be expelled by belching. Some believe that such a bloat is caused by saponins, which are substances that can produce a soapy froth.

The cause of death in bloat is not definitely known. The rise of pressure in the rumen is not apparently great enough to be the chief cause. Some believe that death may be due to the absorption of poisonous compounds produced in the rumen fermentation, or possibly to carbon monoxide or hydrogen sulfide, poisonous gases, which may be formed in small amounts.

It has been found that the juice of certain legumes, such as Ladino clover

or alfalfa, administered to cattle by means of a stomach tube, can cause bloat and also prevent muscular movements, such as produce belching.

One theory of bloat prevention is based on the belief that belching, like rumination, is initiated by stimulation of nerves in the rumen through irritation of coarse feed. When an animal eats a large amount of soft, succulent legume forage, it may not be able to get rid of the gas produced, because this soft forage does not provide the necessary stimulus to cause belching. It is thought that grasses do not cause bloat because the leaves and stems are more irritating or stimulating to the nerves, thus resulting in belching.

Another theory concerning the effect of coarse feed is that it greatly increases the secretion of saliva, and this prevents the formation of froth in the rumen. Whatever the reason is, the consumption of coarse, scratchy feed seems to aid in preventing bloat.

Keeping dairy cows off dangerous legume pasture at night and instead feeding them plenty of coarse but palatable hay, like Sudan hay, or very coarse alfalfa, has prevented bloating. Feeding them straw at night was not effective, because the cows ate but little of it and were ravenous for the legume forage in the morning. Allowing the stock to have access to palatable hay in a rack or stack while on pasture will also help prevent trouble. In a large pasture the hay rack should be in the center, so the cattle have convenient access to it.

Another method is to keep cows on good grass pasture at night and graze them on the legume pasture only during the daytime. Some have advocated keeping cows on the legume pasture day and night, when they are once accustomed to it. However, there is then danger that bloat may occur during the night, and the animal may die before the trouble is noticed.

In some New Zealand trials bloat on legume-grass dairy pastures has been largely prevented by strip grazing, or rationed grazing, in which the cattle are confined by electric fences to a new strip of pasture each day. (377) They then eat all the forage uniformly—grass and legumes, leaves and stems—instead of grazing selectively and consuming too much of the legume tops and leaves.

Sometimes cattle or sheep bloat when fed alfalfa hay along with a heavy allowance of such grain as barley or wheat. The trouble is more apt to occur with very fine, leafy hay than when the hay is coarser and stemmier. Such bloating, which is usually of the frothy type, can generally be prevented by feeding corn silage, beet-top silage, cottonseed hulls, or other palatable nonlegume roughage, in addition to the alfalfa hay, or else by mixing corn, oats, or dried beet pulp with the barley or wheat. Bloat rarely occurs with cattle or sheep fed only alfalfa hay, without grain.

In recent Mississippi trials bloat of cattle on legume pasture was greatly reduced when a mixture of 800 milligrams of procaine penicillin per pound of salt was supplied in a covered salt box, instead of ordinary salt. No other salt was fed.

In severe cases of bloat, prompt treatment is necessary. Sometimes vigorous massaging of the left flank may help, or tying a wooden bit in the mouth may give relief, as the animal will champ its jaws in an effort to get rid of the bit, and this seems to stimulate belching. Some recommend placing the animal with its front feet elevated. Administering a dose of 2 to 4 ounces of turpentine to cattle suffering from bloat often gives relief. Care is necessary to avoid getting the turpentine into the trachea, or windpipe. In the more severe cases, it may be necessary to get rid of the gas by means of a stomach tube, or to tap the rumen and release the gas by means of a trocar, or even with a clean knife, if a trocar is not available.

II. Use of Nutrients in the Body

50. Metabolism.—Through painstaking research, chemists and physiologists have been able to gain much information on the various steps in the digestion of food. When the nutrients

leave the digestive tract and enter the body, the difficulties of learning what becomes of them are much greater. Though many of the changes that occur in the body have been revealed, only a little of a definite nature is yet known concerning other processes.

Metabolism is the term used for all the changes which take place in the nutrients after they are absorbed from the digestive tract. These changes include not only the building-up processes in which the absorbed nutrients are used in the formation or repair of body tissues, but also the breaking-down processes in which nutrients are oxidized for the production of heat and work.

51. Distribution and use of absorbed nutrients.—We have seen that all the digested nutrients are absorbed chiefly by the villi of the small intestine and finally enter the blood circulation. The blood, containing these nutrients, reaches the capillaries in all the body tissues. Here the nutrients can pass through the capillary walls into the lymph that surrounds the body cells. The nutrients then enter the cells, providing nourishment and energy for the various life processes.

The nutrients thus brought to all parts of the body may be used for several purposes. First come the maintenance needs for the preservation of life. These are discussed in detail in Chapter VIII. The daily break-down of the protein tissues must be replaced by the amino acids resulting from the digestion of the protein of the food. Also, some of the nutrients must be oxidized to provide heat for maintaining the body temperature and to furnish energy for the various necessary movements of the body.

If more nutrients are supplied than are needed merely to maintain the body, the following uses can be made of the excess nutrients: (1) They can be made into new body tissue, as in the case of growing and fattening animals; (2) they can be used in the development of the fetus in the case of a pregnant female, and for the formation of eggs in the case of birds; (3) they can be changed into milk, as in the case of dairy cows; or (4) they can be used for the production of muscular work, as in the case of work horses and mules. The uses of nutrients for each of these purposes are discussed in later chapters.

The sugars serve as sources of heat and muscular energy and also as the chief source of the lactose (milk sugar)

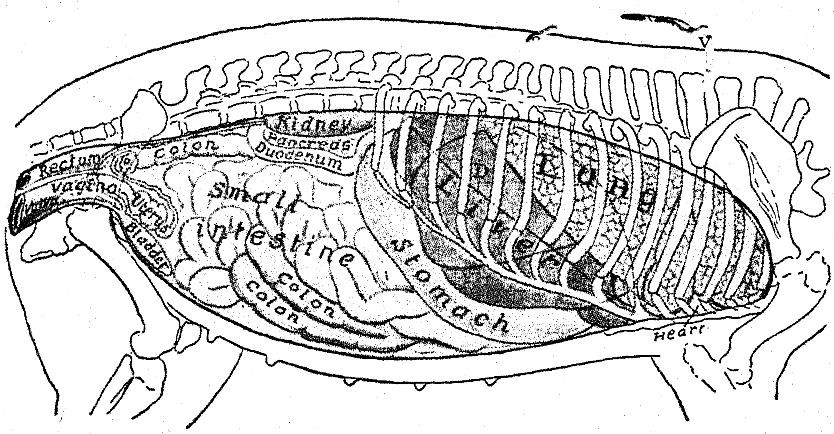


DIAGRAM OF DIGESTIVE SYSTEM OF PIG; RIGHT SIDE

The pancreas and duodenum are not in contact with the flank, as would be inferred from this figure, but are situated nearer the center of the body, and if viewed from the right side, would be covered by the small intestine. (From Sisson, "Anatomy of the Domestic Animals.")

in milk. They can also be changed into body fats. The organic acids produced in the rumen digestion of ruminants can be used somewhat like the sugars. The fats, like the sugars, can furnish heat and energy, and can form body fat and the fat in milk.

If there is a greater supply of amino acids than is needed for body repair or for the building of new protein tissues, the nitrogen (in the form of ammonia) is split off in the liver from the amino acid molecule. The nitrogen is entirely wasted in this process, which is called deaminization, for it is converted into compounds which are excreted in the urine. Also, there is some loss of energy in the nitrogenous waste products. The non-nitrogenous parts of the amino acids that remain can, however, be used in the body for the same purposes as the sugars.

Even when the supply of protein in the food is scanty, a considerable wastage of protein unavoidably occurs for some unknown reason, through the deaminization of amino acids in the liver. Therefore, as is explained in Chapter VIII, more protein must be supplied in maintenance rations than is theoretically needed to replace the daily breakdown of the protein tissues of the body.

It has been previously pointed out that most of the changes in the digestion of food are brought about by enzymes. It is now believed that most other body processes, both the building-up processes and the tearing-down processes, are likewise brought about through enzyme action.

52. Oxidation of nutrients in the body.—Nutrients are constantly being oxidized in the body tissues to provide the energy for all muscular movements and also to furnish heat to maintain the body temperature. These oxidations are produced in the following manner:

In the lungs oxygen is absorbed from the air by the hemoglobin (the red-colored compound in the red blood cells) and is held in loose combination with it. The blood, carrying this oxygen, passes back to the heart and is then carried by the arteries to all parts of the body. In the capillaries the blood gives up oxygen to the body cells.

Many investigations have been conducted by physiologists and biochemists to determine, if possible, the exact changes that take place in the oxidation of the various nutrients in the body. Considerable interesting information has been gained, and various theories have been advanced concerning the steps that occur. For a discussion of these theories the reader is referred to texts on physiology or biochemistry.

For our purposes it is sufficient to state that by intricate processes the carbohydrates, fats, and other nutrients can be oxidized in the tissues to produce energy and heat. In these changes the carbohydrates and fats are eventually oxidized completely to carbon dioxide and water. The carbon dioxide is absorbed by the blood and carried in the veins to the heart, and thence to the lungs. Here it passes off into the air in the lungs and is exhaled, the blood then becoming again charged with oxygen before it flows back to the various parts of the body.

53. Functions of the liver.—The liver, which is the largest gland in the body and which secretes bile, has several important functions. The functions which have already been mentioned in this chapter are: The regulation of the glucose content of the blood through the formation of glycogen; the important part bile has in the digestion and absorption of fat; and the deaminization of amino acids, in which nitrogen is split off in the form of ammonia. The liver also stores vitamin A. It synthesizes fatty acids from carbohydrates or protein, and is important in the use of fat for fuel in the body. The liver protects the body against various poisonous substances, formed in the digestive tract through putrefaction, by changing them into non-poisonous compounds. Among its other functions, it is an important agent in the destruction of worn-out blood cells, and in the formation of blood proteins.

Besides its part in fat digestion, bile probably accelerates the action of the amylase of the pancreatic juice. It also

has a moderately laxative effect and aids in the passage of food through the intestine.

54. Hormones, or internal secretions.—Physiologists have found by extensive investigations that many of the body processes are controlled and regulated by substances called *hormones,* or *internal secretions.* These are produced by the glands of internal secretion, also called the endocrine glands, or the ductless glands.

The secretions of these glands are discharged directly into the blood, or perhaps indirectly by way of the lymph, and are not poured out through a duct, as in the case of the bile and the pancreatic juice. This is the reason why they are referred to as the ductless glands. The hormones are carried in the blood to the parts of the body where they perform their functions. The relations of hormones to such body processes as reproduction, the development of the udder, and the secretion and "let down" of milk are explained in later chapters. Among the important hormones are the following:

Insulin, a hormone produced by the pancreas, is necessary for proper carbohydrate metabolism in the body. Without an adequate supply of this hormone, the ability of the body tissues to oxidize and utilize glucose is decreased. Also, the rate at which glucose is formed from glycogen and from fats and proteins is increased. As a result, the level of glucose in the blood rises, glucose is excreted in the urine, and there are other injurious effects.

The discovery in 1921 of the importance of insulin in carbohydrate metabolism has been of untold benefit to persons suffering from diabetes. In diabetes there is a lack of insulin, with resulting serious consequences. Hypodermic injections of a carefully purified and standardized solution of insulin now bring relief to a patient affected with the disease.

A hormone, called *secretin,* which is produced by the lining of the small intestine, is important in the digestion of food. As soon as the acid, partly-digested food passes from the stomach into the small intestine, the acidity causes the mucous membrane of the small intestine to form secretin. This is absorbed by the blood and carried to the pancreas, where it causes this gland to pour out the pancreatic juice just when it is needed.

The *thyroid gland,* located in the neck, produces *thyroxine,* a hormone that regulates the rate of body metabolism. This hormone has been separated in pure form and found to be an iodine-containing amino acid. As is pointed out in Chapter VI, when there is insufficient iodine in the food the gland enlarges in a desperate effort to manufacture enough thyroxine, and the disease called goiter results.

Thyroprotein, or iodinated casein, which contains thyroxine and other compounds that have a similar effect on body metabolism, is now made commercially by treating milk casein under carefully controlled conditions. Information is given in the chapters of Part III on the use of this product for dairy cows and other classes of stock.

The *parathyroid glands* are very small glands, usually located close to the thyroid gland or imbedded in it. They secrete a hormone which controls the concentration of calcium in the blood. If for any reason the calcium content of the blood is too low, convulsions or paralysis may be caused, as in milk fever of dairy cows.

The *pituitary,* or hypophysis, a small gland at the base of the brain, has several essential functions. Hormones produced by the pituitary seem to stimulate the other glands of internal secretion and thus regulate many body processes. The pituitary is therefore often called the master gland of the body. A hormone produced by the anterior, or forward, part of the gland controls the growth and development of animals and therefore determines the mature body size. If the gland is too active, the body may be of giant size, and on the other hand an insufficiency of the hormone will dwarf the size.

This part of the gland likewise produces certain sex hormones and a hor-

mone that is necessary to start milk secretion in the female. (298) It is also believed to be concerned with the activity of the thyroid gland and other glands. The posterior, or rear, portion of the gland secretes a hormone that stimulates the contraction of the smooth, or involuntary, muscles. This hormone causes the "let down" of milk in dairy cows. (1093)

The *adrenal glands,* or suprarenals, which are two small glands located close to the kidneys, produce various hormones. One of these helps to keep the glucose content of the blood constant by regulating the rate at which glycogen is changed into glucose. Another hormone produced by the adrenal glands seems to be necessary for lactation; a third, for controlling the concentration of water and mineral salts in the blood and tissues; and a fourth for increasing blood pressure in times of emergency.

The *sex glands* secrete hormones that have important functions. Thus, as is explained in Chapter X, hormones produced by the ovaries are necessary for the growth and development of the mammary glands.

Synthetic compounds have been made that have some of the properties of natural sex hormones. Recently, there has been much interest in the use of certain of these compounds in the commercial fattening of poultry, beef cattle, and sheep. The use for this purpose of diethylstilbestrol (commonly called stilbestrol) and of other hormones is discussed in the chapters dealing with these classes of stock.

Recent investigations have shown that certain hormones naturally present in some feeds may affect livestock production.[8] These studies have indicated that the favorable effects of young, actively-growing pasture on milk production and growth may be partly due to hormones the plants contain. At late stages of growth such effects were not found. In other experiments certain lots of alfalfa hay, clover hay, and soybean oil meal had a favorable hormone-like effect.

In one case a hormone naturally present in plants has a very injurious effect. Serious breeding troubles have been caused in Australia in sheep grazing on pasture containing chiefly subterranean clover, with little grass in the mixture. (483)

55. Disposal of body waste.—The undigested food and certain waste products accumulate in the rear part of the large intestine in the form of a more or less solid residue. This is expelled as the feces. The feces of farm animals consist chiefly of undigested food that has never really been within the body proper. This undigested food is mostly cellulose and lignin. Also, a portion of the other nutrients usually escapes digestion. This may be due to insufficient chewing of such food as seeds, or because some nutrients are protected from the digestive juices through being enclosed in resistant cell walls.

In addition to undigested food the feces also contain residues from the digestive fluids, waste mineral matter, worn-out cells from the intestinal lining, mucus, and bacteria. They may also contain such foreign matter as dirt consumed along with the food. In the case of man and of such animals as dogs and cats, the greater part of the feces consists of excretory products, rather than undigested food.

Nearly all of the nitrogenous waste, resulting from the break-down of protein material in the body, is excreted in the urine through the kidneys, though a trace is given off in the sweat and a more appreciable amount in the feces. In mammals this waste chiefly takes the form of urea, while in birds it is excreted chiefly as uric acid.

A great variety of other end-products of metabolism are likewise eliminated by the kidneys through the urine. Some of the mineral matter is excreted in the urine. However, calcium, magnesium, iron, and phosphorus are voided chiefly in the feces. Small amounts of most of the substances eliminated in the urine are also excreted by the skin through the sweat glands.

A large amount of carbon dioxide is formed in the oxidation of the nutri-

ents within the body for the production of heat and energy. Most of this passes into the capillaries and is carried in the blood by the veins to the lungs, where it is eliminated in breathing. A portion, however, escapes by way of the skin. Some of the methane produced by fermentations in the stomach of herbivora is absorbed into the blood and thrown out by the lungs.

56. Importance of quiet, kindness, and regularity.—Farm animals are creatures of habit, and when once accustomed to a certain routine, they show unrest at any decided change. The stable or feed lot should therefore be free from disturbance. The good stockman is kind to his animals and they trust him, but stock may fear a rough or careless person.

Feed and water should be supplied regularly, and large changes should be made gradually. Animals know when meal time has come, and they fret if feeding is delayed. Investigations with human beings have shown that worry and excitement cause a definite decrease in the completeness with which foods are digested. It is reasonable to believe that the same is true in the case of farm animals. At least, there is no question but that unusual excitement may seriously cut down the milk production of dairy cows and reduce the gains of fattening stock.

57. Importance of palatability.—The palatability of feeds is a factor of no small importance in the efficient feeding of stock. It seems possible that well-liked feeds are digested somewhat better than those which are equally nutritious, but less palatable.

From an entirely different standpoint, palatability is of great importance in feeding animals for large production. Unless the ration is palatable, dairy cows or fattening stock will not eat enough feed to permit them to produce milk or meat economically. Feeds which are unpalatable should therefore be used chiefly for stock not being fed for production. For example, idle horses can be wintered largely on straw or on hay of rather poor quality. If a limited amount of unpalatable feed is mixed with some well-liked ingredient, stock will often eat the entire mixture readily.

Familiarity and habit are important factors concerned with the palatability of feeds. Not infrequently, when corn silage is first placed before cows, after sniffing it they will let it alone for a time. They then usually begin nibbling at it, and later eat it with great relish. In such cases, food that at first seems unpalatable finally becomes palatable. Sometimes animals which are used to yellow corn will at first refuse white corn or vice versa. If they are accustomed to whole grain, it may take them a little time to become used to ground grain.

Sometimes the failure of animals to continue to eat a normal amount of feed may indicate a serious nutritive deficiency. For example, if thrifty pigs are fed a ration made up of palatable feeds, but which is deficient in vitamin A or in certain minerals, they may eat normal amounts of food for a time and make satisfactory gains. Then, when the body reserves of the lacking nutrient are exhausted, they will usually consume much less feed, due to an impairment of their health and a consequent lack of appetite. Provided that the deficiency is not continued so long that the pigs are injured permanently, they will usually recover their appetites, if some feed is added which supplies the nutritive lack and makes the ration complete.

Usually feeds that are palatable are safe and nutritious. However, in rare instances this may not be true. For example, sorghum which has been stunted by drouth may contain sufficient prussic acid to kill stock in a few minutes, and yet it will be palatable and will be consumed with eagerness. However, stock generally avoid poisonous plants instinctively and eat them only when impelled by hunger.

QUESTIONS

1. Define *digestion*. What is the nature of the changes produced in food during digestion?
2. Define *enzymes*. Describe a typical enzyme action.

3. Describe the digestive tract of cattle and compare it with that of pigs and of horses.
4. State the essential facts concerning the circulation of the blood; of the lymph.
5. What are the villi of the small intestine and what is their function?
6. Of what importance is thorough mastication of the food?
7. Describe briefly the process of rumination.
8. Describe the digestion and absorption of carbohydrates in non-ruminants. State the enzymes or agents concerned, the place where digestion takes place, the substances acted on, and the products formed.
9. Discuss the formation and function of glycogen.
10. Describe the digestion of cellulose and pentosans by ruminants and by horses. Follow the same outline as for carbohydrates, above.
11. What deficiences in the food may decrease digestion in the rumen?
12. Describe the digestion and absorption of protein, following the same outline.
13. Describe the digestion and absorption of fats, following the same outline.
14. What can be said concerning the digestion of minerals?
15. Summarize the information on the cause of bloat and ways in which it may be prevented.
16. Define *metabolism.*
17. How are the absorbed nutrients distributed to the body tissues?
18. What functions are performed by the absorbed sugars; the fats; the amino acids?
19. Describe the oxidation of nutrients in the body.
20. What are the functions of the liver?
21. Give an illustration of the action of a hormone.
22. Describe the disposal of the various waste products of the body.
23. Discuss the importance of quiet, kindness, and regularity in stock feeding.
24. Of what importance is the palatability of feeds?

CHAPTER III

MEASURING THE USEFULNESS OF FEEDS

I. Determining the Relative Values of Feeds

58. Methods of measuring the values of feeds.—In computing balanced rations for livestock we must know the amounts of nutrients furnished by the various available feeds. Also, in order to plan an efficient cropping system on a stock farm, we must have accurate information concerning the actual feeding value of the various crops that can be grown.

The simplest method of measuring the value of any feed is to determine the amounts of digestible nutrients that it supplies. This method is explained first in this chapter. A method that is theoretically more accurate, but which is much more complicated and expensive, is to determine the amount of net energy supplied by the feed. This method is discussed later. (68–73)

Neither of these chemical methods takes into consideration all the factors which determine the true value of any feed for a particular class of livestock. The only way in which this can be done is to conduct actual feeding experiments under practical conditions with this class of stock. In these tests the relative value of the particular feed can be found, in comparison with that of a standard feeding stuff.

The American experiment stations have conducted many hundreds of such feeding experiments to determine the actual values of the most common feeds and of different rations for the various classes of farm animals. It is of great financial importance to stock farmers to have definite information readily available concerning the value of the various feeds for each class of animals. The author has therefore spent much time in compiling the results of these numerous experiments in order to draw reliable conclusions concerning the relative values of the different feeds.

A single experiment, no matter how carefully planned and conducted, does not give reliable information about the relative value of different feeds or rations. This is because various lots of any feed may differ appreciably in composition, as is emphasized in Chapter IV. Also, individual animals differ in productive capacity. To draw safe conclusions concerning the value of any feed, it is therefore necessary to study and analyze carefully all the available information.

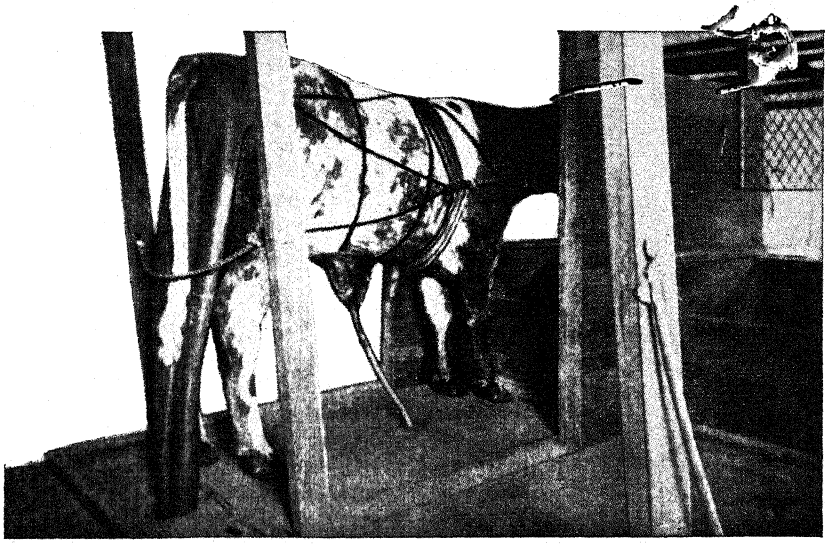
In Part II of this volume detailed information is given about the usefulness and value of all of the important feeds for each of the classes of livestock. Wherever data are available, definite statements are made concerning the relative value of each feed, based on the results of actual feeding experiments that have been conducted under practical conditions.

59. Value of a feed may differ for various animals.—In the discussions of the various feeds in Part II, it will be noted that in several instances the actual value of a particular feed for two classes of stock may differ considerably. For example, a ton of good corn silage is worth 33 to 40 per cent as much as a ton of legume or mixed hay for dairy cows. For fattening cattle and lambs silage has a higher value, being worth fully one-half as much per ton as good hay.

Similarly, ground barley is about equal to ground corn for dairy cows, but for swine or for fattening cattle or lambs its relative value is appreciably lower. Also, barley injured by the scab disease is satisfactory for cattle and sheep, but it is unsuited to horses and pigs.

Another interesting example is the

fact that cottonseed meal of the usual kind can be fed safely to cattle in large amounts, if plenty of vitamins and minerals are provided. On the other hand, pigs should be fed only limited amounts of such cottonseed meal, or disastrous results may follow. Again, uncooked field beans give satisfactory results when forming not too large a part of the ration for dairy cows, beef cattle, and sheep, but pigs do poorly on beans unless they are cooked.



A STEER IN A DIGESTION STALL

In digestion trials the feces may be collected in several ways. A common method is by means of the harness and rubber duct here shown. When it is merely desired to determine the digestibility of a feed, the urine need not be collected, as is being done in this trial. (From Pennsylvania Station.)

Such differences as these may not be shown at all by determinations of the amounts of digestible nutrients or of net energy in a feed. They can be revealed only by actual experiments with the particular kind of animal in question. These examples show that in order to feed any class of stock most efficiently one must not only consider the amounts of nutrients supplied by various feeds, but also must know the results that are actually produced when these feeds are fed to that class of stock.

60. Digestion experiments and digestion coefficients.—The digestibility of a particular feed for any class of stock is determined by means of digestion experiments with that kind of animal. The chemist first finds by analysis the percentage of each nutrient the feed contains. The animal is then fed weighed quantities of the feed for a preliminary period of a few days, so that all residues of former feed may pass out of the digestive tract.

During the digestion experiment the same amount of the feed is given to the animal each day. The feces are carefully collected and weighed, and samples are analyzed. The differences between the amount of each nutrient fed daily and the amount found in the feces is the amount of the nutrient that is digested. From this information, there is computed the percentage of each nutrient which is digested from the feed.

The percentage of each nutrient digested in a feed is called the *digestion coefficient* for that nutrient in the feed.

To show how the digestibility of a feed is determined, let us suppose that during a 10-day digestion experiment, a

cow was fed 20 lbs. of clover hay each day, containing 13.26 per cent of protein. This amount of the hay would therefore contain 2.65 lbs. of protein. During the experiment the cow excreted, on the average, 47.3 lbs. of feces daily, which contained 2.32 per cent protein, or a total of 1.10 lbs. of protein.

Subtracting 1.10 lbs. (the amount of protein in the feces) from 2.65 lbs. (the amount of protein in the 20 lbs. of hay fed daily), we find that 1.55 lbs. of protein were digested. Next, we divide 1.55 lbs. by 2.65 lbs. and multiply the quotient by 100, to find the digestion coefficient for protein in the hay, or the percentage of the protein digested. This is 58.5 per cent. The digestion coefficients for the fat, fiber, and nitrogen-free extract in the feed are found in a similar manner.

In the case of feeds for which no digestibility data are available, Schneider and associates have developed formulas for estimating digestion coefficients of various classes of feeds from the chemical composition of the particular feed.[1]

61. Determining digestibility by difference.—Some feeds cannot be fed alone, as was done in this experiment. Thus, horses and ruminants are not fed concentrates alone, without hay or other roughage. Again, while pigs may be fed on grain only, such feeds as tankage and linseed meal are too rich in protein to be fed alone. The digestibility of such feeds must therefore be found by difference, instead of directly.

For example, in an experiment to determine the digestibility of oats for sheep, a sheep is first fed hay for several days, and the digestibility of the hay found. Then oats are added to the ration, and the total amounts of nutrients are determined that are digested from the combination of oats and hay. The amounts of digestible nutrients coming from the hay are then subtracted from the total, leaving the amounts which are assumed to be digested from the oats.

62. Digestion coefficients in Appendix Table I.—Individual animals of the same species vary somewhat in their ability to digest any given feed. It is therefore essential, in computing the digestible nutrients in feeds as a guide for stock feeding, to use average digestion coefficients that are based on all representative digestion trials which have been conducted.

The author has made for this edition of *Feeds and Feeding* a new compilation of the digestion coefficients for the various feeds that have been determined in the many trials by the American experiment stations. The average digestion coefficients are presented on the right-hand pages of Appendix Table I.

In the case of feeds for which American data are not available or are very limited, digestion coefficients obtained in experiments in other countries have been included. Especially useful in such cases has been the extensive compilation made by Schneider of digestion coefficients obtained in experiments in various countries.[2]

It will be noted, on inspecting the digestion coefficients for various feeds given in Appendix Table I, that feeds which contain but little fiber, such as corn and wheat, are highly digestible. This is because the cell walls are thin and are easily penetrated by the digestive juices. The more fiber a feed contains, generally the thicker and more resistant are the cell walls, and consequently the lower is the digestibility of the feed. Thus, oats and bran are somewhat less digestible than corn and wheat, and the roughages have considerably lower digestion coefficients.

It is pointed out in Chapter XIII that young pasture forage is much more digestible than the same plants at later stages of growth. (358) The difference is especially great when the plants become mature and is still greater if the mature plants are weathered by exposure. This difference in digestibility as plants grow older is due to a considerable extent to increase in lignin, which is nearly indigestible, even by ruminants.

The nitrogen-free extract in the cereal grains and in most other high-grade concentrates is considerably more digestible than the fiber. On the other

hand, in such roughages as the grasses and corn or sorghum forage, the fiber may be more digestible than the nitrogen-free extract. This is probably because these roughages have considerable lignin, and much of the lignin, though mostly indigestible, is unfortunately included in the nitrogen-free extract in the usual method of feed analysis. Information about the digestibility of various feeds is given in the detailed discussions about the individual feeds in Part II.

As has been explained in the previous chapter, cattle and sheep digest feeds high in fiber more completely than do horses and swine. In spite of this difference, the digestion coefficients obtained in tests with cattle and sheep are commonly used in computing rations for horses and swine, because only a few digestion trials have been carried on with the latter animals. However, no error of importance is involved in this, for the recommendations in modern feeding standards take this fact into consideration.

63. Digestible protein; total digestible nutrients.—To find the percentages of digestible nutrients in any feeding stuff, the percentage of each nutrient is multipled by the digestion coefficient for that nutrient. For example, dent corn of U.S. Grade No. 1 contains 8.9 per cent of protein (See Appendix Table I), of which 77 per cent is digestible. Therefore the percentage of digestible protein is 6.9. In this manner the data have been computed which are given in the second and third columns of figures in Appendix Table I.

Since protein has special functions in the body which can be performed by none of the other nutrients, the percentages of *digestible protein* are shown separately in the second column. Next are given the percentages of *total digestible nutrients* in the various feeds.

The *total digestible nutrients* is the sum of all the digestible organic nutrients—protein, fiber, nitrogen-free extract, and fat (the latter being multiplied by 2.25, because its energy value for animals is approximately 2.25 times that of protein or carbohydrates). The abbreviation T.D.N. is often used for *total digestible nutrients.*

The percentages of total digestible nutrients therefore represent the approximate heat or energy value of the feed. The digestible protein is included in this total, since protein serves as a source of heat and energy when more is provided than is required to meet the protein needs of the body.

An inspection of Appendix Table I will show the wide differences there are in the amounts of digestible protein and of total digestible nutrients in the various feeds. The cereal grains and other seeds are rich in total digestible nutrients, as are also the by-product feeds that are low in fiber. At a hay stage, grasses and legumes have much smaller amounts of total digestible nutrients than the grains and other concentrates, and the straws are especially low.

On the dry basis, young grass or legume pasture may supply nearly as much total digestible nutrients as some concentrates. For example, young mixed grass and legume pasture from a fertile, well-grazed field may contain 70 per cent total digestible nutrients in the dry matter, in comparison with 80 per cent or more in the dry matter of a good concentrate mixture.

A few feeds, such as flaxseed, which are unusually rich in fat, supply more than 100 lbs. of total digestible nutrients per 100 lbs. of the feed. This is due to the fact that digestible fat is multiplied by 2.25 when it is included in the sum, "total digestible nutrients." For example, the high figure of 108.3 per cent of total digestible nutrients for flaxseed means that 100 lbs. of flaxseed furnish as much heat or energy as would be supplied by 108.3 lbs. of digestible starch.

64. Other methods; digestible energy.—Methods have been recently proposed for reducing the chemical determinations needed to find in a digestion trial the amount of total digestible nutrients in a feed or ration. One method, proposed by Lofgreen,[3] is based on determining only the water, mineral matter, and fat in the feed, and the water and

mineral matter in the feces. The digestibility of the total organic matter is first calculated, and this is then multiplied by a factor based on the percentage of fat in the feed, to give the estimated percentage of total digestible nutrients. This method gave results which agreed well with those determined by the standard method. A somewhat similar method has been proposed by Reid.[4]

Instead of using total digestible nutrients in valuing feeds and computing rations, *digestible energy* can be used.[5] This can be determined by burning samples of the feed and of the feces in a bomb calorimeter. The method is not in general use.

Total digestible nutrients can be calculated from the content of digestible energy, and digestible energy from the content of total digestible nutrients. The approximate energy value of 1.0 lb. of total digestible nutrients has commonly been assumed to be 1,814 Calories. However, according to studies of Schneider and associates of the Washington Station, the value of 1,987 Calories per pound, or 4.38 Calories per gram, of total digestible nutrients is more accurate.[6]

65. Nutritive ratio.—As protein serves special uses in the body, in discussions of feeding stuffs and rations the term *nutritive ratio* is employed to show the proportion of digestible protein.

By *nutritive ratio* is meant the ratio, or proportion, between the digestible protein and the digestible non-nitrogenous nutrients (including fat multiplied by 2.25).

When the percentage of total digestible nutrients is given, as in Appendix Table I, the nutritive ratio is computed as follows: The percentage of *digestible protein* is subtracted from the percentage of *total digestible nutrients* to obtain the percentage of digestible *non-nitrogenous nutrients.* This remainder is divided by the *digestible protein,* the quotient being the second term of the ratio.

The manner of computing the nutritive ratio of Grade No. 1 dent corn is as follows:

Total dig. nutrients Per cent		Dig. protein Per cent		Dig. non-nitrogenous nutrients Per cent
81.9	—	6.9	=	75.0

Dig. non-nitrogenous nutrients Per cent		Dig. protein Per cent		Second factor of nutritive ratio
75.0	÷	6.9	=	10.9

Nutritive ratios are expressed with the colon. The nutritive ratio of dent corn is therefore 1 : 10.9 (read as 1 to 10.9). This means that for each pound of digestible protein in corn there are 10.9 lbs. of digestible non-nitrogenous nutrients, including fat multiplied by 2.25.

A feed or ration having much protein in proportion to the non-nitrogenous nutrients is said to have a *narrow nutritive ratio;* if the reverse, it has a *wide nutritive ratio.* Oat straw has the extremely wide nutritive ratio of 1 : 62.9, because of its low content of digestible protein compared with the carbohydrates and fat. Oat grain has the medium one of 1 : 6.5, and protein-rich soybean oil meal the very narrow ratio of 1 : 1.1, the digestible non-nitrogenous nutrients being less than twice the digestible protein.

Another method of computing the nutritive ratio, which is even simpler than the preceding, is as follows: Divide the percentage of *total digestible nutrients* by the percentage of *digestible protein,* and subtract 1.0 from the quotient. The result will be the second term of the nutritive ratio. For example, the nutritive ratio of Grade No. 1 dent corn is found as follows:

Total dig. nutrients Per cent		Dig. protein Per cent		
81.9	÷	6.9	=	11.9

				Second factor of nutritive ratio
11.9	—	1.0	=	10.9

66. Determining digestibility by other methods.—There has been much interest recently among animal nutrition scientists in methods of reducing the cost and time required in digestion experiments by the use of methods in which the feces are not collected and weighed but are merely sampled and analyzed.

One method is to determine the lignin

content of the forage or ration and the lignin content of the feces. In this method it is assumed that lignin is not digested to any appreciable extent, even by ruminants, and that therefore all the lignin in the feed eaten will be in the feces. The digestibility of the various nutrients can then be determined from the percentage of lignin and of the nutrient in the feed and the percentage of each in the feces. Although it has been found that a small percentage of the lignin in some feeds may be digested by a ruminant, an average correction can be made for this.[7]

In some experiments in which the lignin method has been compared with the standard method, the results have agreed well, but in others the lignin method has been less satisfactory.[8]

In another method carefully weighed amounts of chromic oxide, an inert, indigestible compound, are administered to the animal each day, and the amount in the feces determined.[9]

Reid of the New York (Cornell) Station has developed a method of using a naturally occurring plant pigment, or chromogen, in forage plants as an indicator in digestion experiments.[10] This method is based on the fact that this pigment is apparently entirely indigestible and completely recovered in the feces. This method is proving especially useful in determining the digestibility of the forage eaten by animals on pasture.

By combining the use of the chromogen method and the chromic oxide method or by the chromic oxide method alone, the amount of pasturage dry matter eaten daily can be found.[11] In some such studies, a complete collection of the feces voided daily is made by means of a feces bag attached to the animal. The forage consumption can even be estimated approximately by taking samples of the feces at stated times each day, without total collection.

In still another method, the digestibility of forage is estimated from the nitrogen content of the forage and the feces. This method seems to be less reliable than the chromogen method or the chromic oxide method.[12]

A chemical method in which a sample of feed is digested with enzymes in the laboratory gives approximate information on the digestibility of such feeds as meat and fish by-products.[13]

67. Limitations of digestion trials.—The data secured in digestion trials provide the general basis for our knowledge concerning the amounts of digestible nutrients furnished by the many different feeding stuffs. Such data are therefore highly inportant in the science of stock feeding.

Even the net-energy values of feeds, which are discussed later in this chapter, are usually computed from tables of digestible nutrients, such as Appendix Table I of this volume, by applying certain factors to the values for digestible nutrients. However, in using tables of digestion coefficients and digestible nutrients, it is well to bear in mind that the digestibility of a particular sample of a feed may differ appreciably from the average digestibility for that kind of feed. Also, various conditions may affect the digestibility of a feed or ration.

Information is given in the next chapter concerning the effects upon digestibility of such factors as various methods of preparing feeds, the amount of feed eaten, and the proportion of protein and other nutrients in the ration.

Because of the variations in digestibility of different lots of the same kind of feed, some scientists have doubted whether the use of such average data is advisable. However, from a detailed statistical study of the available data, Schneider and associates concluded that applying average digestion coefficients for a given feed to individual lots of that feed is warranted.[14]

The following information concerning the limitations of digestion trials is of scientific interest:

In digestion trials it is commonly assumed that all matter appearing in the feces represents the part of the food which is actually indigestible. This is only approximately correct, for the feces always contain in addition some waste from the body itself, such as unabsorbed residues from the bile and other digestive juices, worn-out cells and mucus from the membranes lining the digestive tract, and waste mineral matter. The feces also include innumerable living and dead bacteria.

In herbivora, such as cattle and horses, which eat much roughage, these products form but a small part of the feces, while in carnivora, such as dogs, they form a considerable portion. All these constituents of the feces are waste products. Therefore, although they do not represent undigested food, it is

entirely correct from a practical standpoint to deduct them, along with the food that is actually undigested, in determining the digestible nutrients which are of use to an animal. These intestinal waste products which are excreted in the feces are a part of the cost of digesting the feed, as they represent the "wear and tear" of the digestive organs.

In nutrition studies, when it is desired to determine how much of the protein of the feed has actually been digested, the feces may be treated with an acid solution of pepsin. This dissolves practically all the protein compounds in the feces except the true undigested food protein.

It has been pointed out in the preceding chapter that in the digestion of cellulose and pentosans by bacteria in the paunch of ruminants and to a less extent in the large intestine of other animals, some of the carbohydrates are broken down into carbon dioxide and methane, gases that have no nutritive value. Yet, due to the method of computing digestible nutrients, these are commonly included in the amount of carbohydrates considered digestible. This does not involve any serious error even with ruminants, and with other classes of stock the discrepancy is usually negligible.

Errors are apt to occur in determining the digestibility of the ether extract, or so-called "fat," for fat is usually present in feeding stuffs in much smaller amounts than protein and carbohydrates. Furthermore, as has been pointed out in Chapter I, ether dissolves not only true fat but also such plant compounds as chlorophyll and waxes. It also dissolves such products in the feces as the bile residues.

The true fats are highly digestible, but the waxes, etc., are of rather low digestibility. Fraps and Rather, on studying the ether extract obtained from 18 different forage plants, found that only 42 per cent was true fat.[15] Of this, 66 per cent was digested, while only 29 per cent of the remainder (not true fat) was digestible.

Certain forage plants of the western ranges, such as the sagebrushes, have a high content of essential oils. (**14**) Though these essential oils have little or no energy value to the animal, they are included in the fat in the usual feed analysis. The actual feeding value of such plants is consequently less than shown by the content of total digestible nutrients.[16]

The ordinary digestion trials give little information concerning the extent to which the mineral matter is actually digested and absorbed, because calcium, magnesium, phosphorus, and iron are chiefly excreted from the body in the feces. Therefore, in a digestion trial these compounds would be reported as largely undigested, though they may really have been digested and absorbed, and later excreted in the feces after being used in the body.

By the use of radioisotopes, such as radiocalcium, the true digestibility of these minerals can be determined. In a digestion trial of this kind, it was found that month-old calves fed milk digested over 90 per cent of the calcium; mature cattle on rations of grain and hay, 30 to 40 per cent; and aged cattle, only 22 per cent.[17]

II. Net Energy and Metabolizable Energy

68. All losses not deducted in digestible nutrient values.—It has been shown previously in this chapter that in determining the amounts of digestible nutrients in a feed, the only loss of nutrients which is deducted is the loss that occurs in the undigested material in the feces. It is assumed that the remainder—the digestible nutrients—is all assimilated and used in the body.

However, this is not strictly true. Energy losses of three other types occur in the digestion and utilization of food. These are:

1. Energy is lost in the urea and other nitrogenous waste products that are excreted in the urine. These compounds have energy value which is lost to the animal. (**51**) This loss of energy is small in the case of feeds which are low in protein and is not very great even in the case of feeds rich in protein.

2. A small amount of energy is lost in the combustible gasses, especially methane, which are produced in the fermentations of cellulose, pentosans, and other carbohydrates in the digestive tract, particularly in the paunch of ruminants. (**44**) The amount of energy lost by this means does not differ much for the various common feeds and is no greater for roughages than for grain and other concentrates. Even in the case of cattle and sheep, the loss is generally less than 10 per cent of the total energy in the feed.

3. A much greater loss of energy

occurs in the various necessary processes of chewing, digesting, and assimilating the food. This is often called the "work of digestion." It is easy to see that energy is required for the movements of the jaws in chewing, for the movements of the digestive tract, and for the increased work of the heart and lungs during digestion. Also, the secretion of the digestive juices requires energy, and there are losses of energy in the heat produced through the bacterial action upon carbohydrates. The energy expended in these processes all takes the form of heat, and it may help to warm the body, if sufficient heat is not otherwise being produced in the body. However, it cannot be used for other purposes, because the body has no ability to convert heat into other forms of energy.

In addition to these losses of energy due to the actual work of chewing, digesting, and assimilating the food, a further loss occurs through the speeding up of the body processes which always follows the eating of food. It has been found that while nutrients are being absorbed from the digestive tract following a meal, more heat is produced than at other times.

This effect is familiar to all of us, for we know that if we eat a meal when we are chilly, we will soon feel decidedly warmer. Likewise, if we eat too heartily in hot weather, we will suffer even more from the heat.

As stated previously, all the losses of energy in the form of heat are often called the "work of digestion." Scientists more commonly use the term *heat increment* to include all these losses, for they are due to the increase, or increment, in heat production of the body that results from the consumption of food.

The *heat increment* is the additional amount of heat which is produced in the body following and because of the consumption of food. It should be borne in mind that it is not the total amount of heat produced in this period, but only the additional amount in excess of the heat produced during a similar period of time before the food was eaten, or in a period when less food was consumed.

The losses of energy in the heat increment are much greater in the case of feeds that are high in fiber than with grain and other concentrates that are low in fiber and therefore readily digested. For example, about 33 per cent of the energy in the nutrients digested from corn grain is used up in this "work of digestion," while this loss is approximately 60 per cent in the case of wheat straw.

69. Net-energy values.—After there is deducted from the total or gross amount of energy in a feed, the energy lost in the feces and by these three other means, there remains what is called the *net-energy value*. This represents the real value of the feed for productive purposes, such as producing growth, body fat, milk, or wool, or in the performance of work. To fix in mind the exact meaning of net-energy values, the following definition should be learned.

The *net-energy value* of a feed is the amount of energy left after there are deducted from its total energy value the amounts of energy lost in: (1) Feces; (2) combustible gases; (3) urine; and (4) heat increment, or "work of digestion."

A certain amount of the net energy supplied by the food must be used to meet the daily maintenance needs of the animal. Even when an animal consumes no food, a certain amount of energy is required for the necessary functions of the body. These include the work of the heart, the lungs, and the other internal organs, as well as the work done by the muscles in producing the movements of the body.

If there is a surplus of net energy left after meeting the requirements for merely maintaining the body, then this surplus may be used for growth, for the formation of body fat, for the production of milk or wool, or for muscular work.

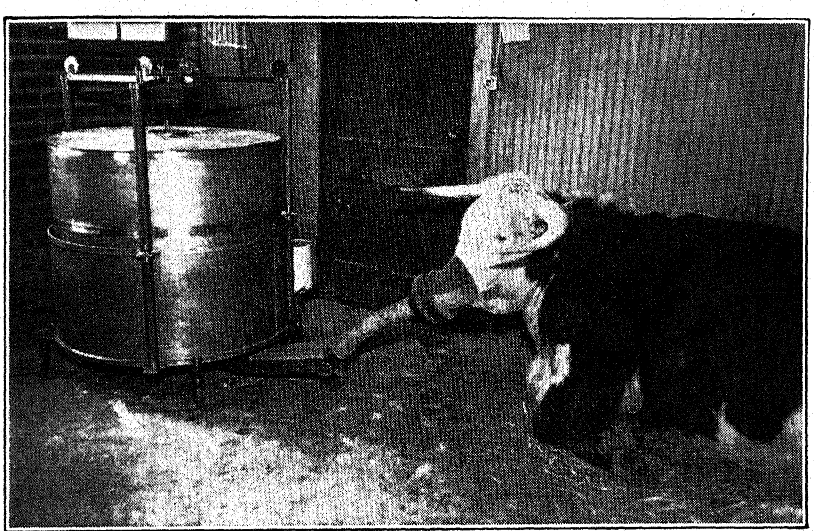
The net-energy value of a feed does not measure its value for maintaining an animal when the weather is cold. This is because no credit is given for the fact

that the heat produced in the "work of digestion" helps to keep the animal warm.

When the temperature of the air surrounding an animal is comfortably warm, enough heat is produced to keep it warm through the oxidations that are always taking place in the body, even when no food is eaten. Under these conditions it gets no benefit at all from the additional heat produced because of the consumption of food (the heat increment).

the remainder is called the *metabolizable energy*. (This is sometimes called *available energy*.) Metabolizable energy shows the value of a feed for maintaining the body temperature, but it does not measure its value for productive purposes.

71. Net-energy values expressed in therms.—In this country the net-energy values of livestock feeds are commonly expressed in therms. A therm, which is a unit for measuring heat, is the amount of heat required to raise the temperature



A SIMPLE TYPE OF RESPIRATION APPARATUS

In this type of respiration apparatus, the air-tight mask over the nose and mouth of the animal is connected to a measuring air-tank. The amount of oxygen used up can be measured, while the carbon dioxide breathed out is absorbed chemically. (From Brody, University of Missouri.)

of 1,000 kilograms of water 1° Centigrade, or to raise the temperature of 1,000 lbs. of water about 4° Fahrenheit.

In studies of human nutrition, the Calorie is used as the unit for measuring heat. The Calorie, known as the large Calorie, is written with a capital C to distinguish it from the calorie (small calorie). One therm is 1,000 Calories or 1,000,000 small calories.

In Europe, net-energy values are generally expressed in terms of starch values, which are explained later in this chapter.

70. Metabolizable energy.—Only the losses of energy in the feces, the combustible gases, and the urine are total losses to an animal. As has been stated previously, the energy used up in the so-called "work of digestion" is all converted into heat. It thus helps to keep the animal warm, if sufficient heat is not otherwise being produced in the body.

For this reason, sometimes only the losses of energy in feces, combustible gases, and urine are deducted from the total amount of energy in the feed, and

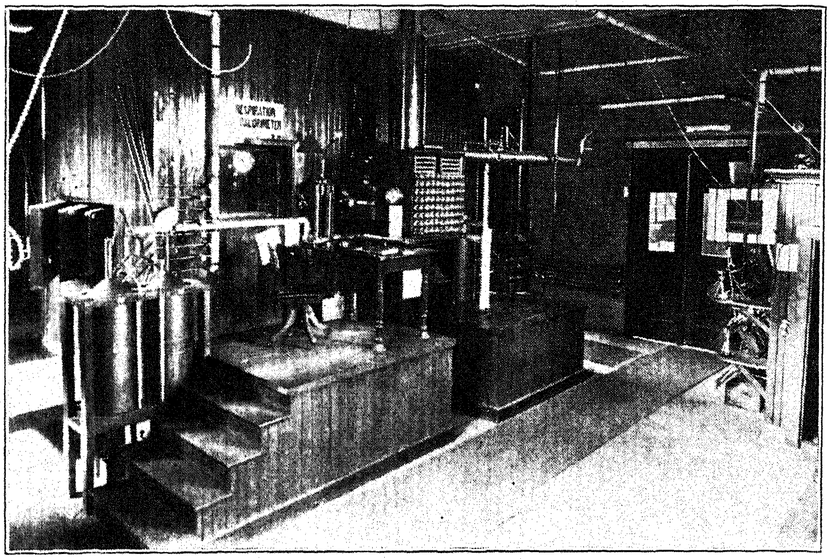
72. Determining net-energy values of feeds.—It is much more difficult and expensive to determine chemically the net-energy value of a feed than to find the amount of total digestible nutrients it supplies. For this reason, the net-energy values of only a very few feeds have been thus found.

First, the gross energy value of the feed is found by burning a weighed sample in pure oxygen gas in an apparatus called a calorimeter, in which the heat given off can be determined accurately. Next, the energy losses in feces and urine are found by collecting and drying these excreta and burning samples in a calorimeter.

It is much more difficult to find the energy lost in the combustible gases and in the heat increment. These losses can be determined only by means of a *respiration apparatus* or a *respiration calorimeter.*

In the simplest type of *respiration apparatus,* the animal breathes through a mask placed over its nose and mouth. The amount of oxygen in the incoming air and in some cases the amount of carbon dioxide breathed out are carefully determined. The energy lost in the combustible gases is not determined in this sort of apparatus, but can be computed from data obtained in other experiments, since this loss is small and relatively constant for any type of animal.

Apparatus of this kind is now used in most large hospitals to find the rate of metabolism in humans suffering from certain diseases. This method has been used in extensive studies by Brody and associates at the Missouri Station to find the energy expenditure of farm animals of various classes and under different conditions.



RESPIRATION CALORIMETER AT PENNSYLVANIA STATION

Much important information concerning the nutritive values of different classes of feeds has been secured through the investigations conducted with this apparatus. (From Pennsylvania Institute of Animal Nutrition.)

In the more complete type of respiration apparatus, the animal is confined in an air-tight chamber, equipped so that the air entering and leaving can be accurately measured and analyzed. Extensive studies with farm animals have been made by Kellner, Möllgaard, and other European scientists with apparatus of this kind, and in this country by Ritzman and successors at the New Hamp-

shire Station, by Mitchell at the Illinois Station, and by Kleiber at the California Station.

The *respiration calorimeter* resembles this latter type of respiration apparatus, but in addition is equipped with elaborate devices by means of which the heat given off by the animal can be directly determined. The only respiration calorimeter built in this country for experiments with farm animals was erected years ago by Armsby at the Pennsylvania Station. After his death, the investigations were continued by Forbes and associates and later by Swift and associates. During recent years this respiration calorimeter has unfortunately been used but little, because of the great amount of time and expense required in such experiments.

Another method of determining net-energy values is to analyze the entire bodies of growing animals that have been fed the test ration during an experimental period of sufficient length. This method has been used by Fraps of the Texas Station to determine the net-energy values of various feeds for growing chickens.[18] It would be very difficult and expensive to use the method with the larger farm animals.

Approximate net-energy values can be determined rather easily by a method proposed by the author of this volume. In this method, which is described later, certain modifications are made in the usual type of practical feeding experiment. (81) Other feeds are directly compared with corn grain as a standard, since reliable net-energy values for corn have been determined in energy investigations.

The approximate net-energy value of any feed for a particular class of stock can also be computed, if a sufficient number of ordinary feeding experiments have been conducted to compare this feed with other standard feeds. This is the method that has been chiefly used by the author in computing the estimated net-energy values given in Appendix Table II of this volume.

Moore and associates have also developed formulas for estimating the net energy values of various feeds from the content of total digestible nutrients.[19] Data are insufficient to determine whether these formulas can be used for feeds very high in fiber, such as peanut hulls.

73. Net-energy values of nutrients and typical feeds.—The various losses of energy that occur in the use by cattle of pure digestible nutrients and of typical feeds are shown in the following table. This is based on the investigations by Kellner with a respiration apparatus and by Armsby with the respiration calorimeter.

It will be noted that peanut oil, a fat, had much more gross energy than the other nutrients. This is because fats contain a much larger proportion of carbon and hydrogen and less oxygen than do carbohydrates or protein. The gross-energy value of protein is also somewhat higher than that of carbohydrates.

In the case of the pure nutrients, peanut oil or wheat gluten, there was no loss of energy in the form of combustible gases because fat and protein, as such, do not undergo the fermentations in the paunch and large intestine which produce these gases. However, in the case of starch, a loss of 17.3 therms of energy occurred in combustible gases for each 100 lbs. of the nutrient. No loss of energy in the urine resulted in either peanut oil or starch since they contained neither protein or other nitrogenous compounds.

With ruminants fed pure nutrients such as fat, protein, and carbohydrates as used in these experiments there are losses in the feces and other excreta of the body. This loss amounted to 188.8 therms for peanut oil, 55.4 therms for wheat gluten, and 33.6 therms for starch. (When these same nutrients are fed to simple stomached animals, such as swine, much better utilization is secured and the losses in this manner are negligible.)

After all of these various losses were deducted there remained 241.0 therms of *metabolizable* energy for the fat, 164.5 therms for the protein, and 137.5 therms for the starch. The losses in heat increment, often incorrectly called, "work of digestion," were highest in the case of

protein and lowest for starch. Deducting all losses, there remained 163.8 therms of energy from 100 lbs. of fat; 68.3 therms from protein; and 81.0 therms from starch.

It is important to note that although protein contained considerably more gross energy than did starch, the losses were so much larger that it furnished a less amount of net energy. The net-energy value of protein represents the value of food protein that is supplied in excess of the actual needs of the animal for protein. It is the worth of protein as a substitute for starch or fat in the production of heat, energy, or body fat. Protein has its full value only when used for the repair of protein tissue, for the building of new body protein, or for making the protein in milk.

It should be noted that in computing the total digestible nutrients of feeds, digestible protein is given the same value as digestible carbohydrates, instead of being given any higher value.

Practical feeding experiments which are reviewed in later chapters have shown clearly that a protein supplement such as soybean oil meal or cottonseed meal has a much higher value than corn grain, when the necessary amount is added to balance a protein-poor ration. However, when a large amount of the protein supplement is fed as a corn substitute, the excess amount is usually worth a little less than corn, instead of more than the grain.

74. Net-energy values of concentrates and roughages.—The table shows that wheat straw, which is a very low-grade feed, has fully as high a gross-energy value per 100 lbs. as does ground corn or timothy hay. This means merely that it will produce as much heat on being burned. While the gross-energy values of these feeds are approximately the same, there are great differences in the losses which occur in them.

Net energy value of pure nutrients and typical feeding stuffs (for ruminants, per 100 lbs., air-dry basis)

Nutrients or feeding stuffs	Gross energy	Energy lost in: Feces & other excreta	Urine	Combustible gases	Metabolizable energy remaining	Heat increment	Net energy
	Therms	Therms	Therms	Therms	Therms	Therms	Therms
Pure nutrients							
Peanut oil (fat)	429.0	188.8	0.0	0.0	241.0	77.2	163.8
Wheat gluten (protein)	253.1	55.4	33.2	0.0	164.5	96.2	68.3
Starch (carbohydrate)	188.4	33.6	0.0	17.3	137.5	56.5	81.0
Common feeding stuffs							
Ground corn	177.7	18.6	8.0	17.8	133.3	51.5	81.8
Timothy hay	182.4	86.9	7.3	13.4	74.8	31.0	43.8
Wheat straw	186.7	109.6	3.7	15.5	57.9	48.5	9.4

In the case of corn, which is highly digestible, only 18.6 therms of energy were lost in the feces. Because of the lower digestibility of hay, 86.9 therms were lost in the feces per 100 lbs. of timothy hay. Wheat straw was digested so poorly that more than one-half of the original gross-energy content was lost.

There was little loss of energy in the urine with all of these feeds, for none of them is high in protein.

The loss of energy in combustible gases was also small for all of the feeds, amounting to less than 10 per cent of the gross-energy content.

Deducting the losses in feces, combustible gases, and urine, there remained 133.3 therms of *metabolizable energy*

from 100 lbs. of corn; 74.8 therms from hay; and only 57.9 therms from the straw. After the energy lost in heat increment is subtracted from the metabolizable energy for these feeds, the energy remaining, or *net-energy* value is 81.8 therms, for corn; 43.8 therms for hay; and 9.4 therms for straw.

It is sometimes said that no more energy is lost in the "heat increment" per 100 lbs. in the case of roughages than with corn or other concentrates. While this is literally true, it is a misleading basis of comparison. The comparison should be made on the basis of the *proportion* of the metabolizable energy which is lost in the "heat increment."

Comparing ground corn and wheat straw on this basis, it will be found that in the case of the straw 84 per cent of the metabolizable energy was lost in the heat increment. With the ground corn only 39 per cent of the metabolizable energy was lost by this means.

These data show that for productive purposes, such as the formation of body fat, 100 lbs. of wheat straw were worth less than one-eighth as much as 100 lbs. of corn grain and only one-fourth as much as 100 lbs. of timothy hay. For the production of heat in the body, the relative values of these feeds are measured by their metabolizable-energy values. Total digestible nutrients furnished by various feeds are also approximate measures of their relative values for this purpose.

75. Maintaining animals in cold weather.—It has been mentioned previously that net-energy determinations are practically always made with animals in an air temperature such that they get no benefit from the heat lost in the "heat increment." (68) For this reason such net-energy values should not be used in computing maintenance rations for wintering farm animals in sections where the winter climate is cold. It is shown in Chapter VIII that the chief maintenance requirement in cold weather is for heat to keep the body warm. The usual net-energy values seriously undervalue the worth of roughages for this purpose. In computing rations for maintaining stock in winter, it is therefore more accurate to use total digestible nutrients. Metabolizable-energy values are also suitable for this purpose, but are not in common use.

The fact that roughages have a much higher relative value for warming the body than they do for productive purposes, is of great importance in livestock feeding. It is pointed out in later chapters that mature animals that are merely being maintained, such as idle horses in winter, can be satisfactorily kept on roughages alone, even those of rather low quality. On the other hand, high-producing dairy cows, fattening cattle or sheep, and horses at hard work can make but little use of low-grade roughage, such as straw or poor, woody hay.

76. Metabolizable energy for valuing feeds.—Some investigators advocate the use of metabolizable-energy values for valuing various feeds and for computing rations, instead of net-energy values or total digestible nutrients.

Except in the case of poultry, this does not seem desirable to the author. As is pointed out in Chapter XXXVI, in poultry the feces and urine are not voided separately. It is therefore impossible to determine the digestible nutrients by the usual methods. However, the metabolizable energy in a ration can be found by determining the energy content of the feed and of the combined feces and urine. Metabolizable-energy values are therefore useful measures of the values of poultry feeds.

In the case of other farm animals, metabolizable-energy values do not furnish a much better index to the relative values of feeds high in fiber and those low in fiber than do total digestible nutrient values. It is much more difficult to determine metabolizable-energy values experimentally, than to find the digestibility of feeds. Some have advocated the computation of metabolizable-energy values from the amounts of digestible nutrients by the use of various factors.[20] Such computed values can be only very approximate. Therefore the author prefers to use either total digestible nutrients, with their acknowledged

limitations, or else to use estimated net-energy values, such as are given in Appendix Table II.

It should be borne in mind that in the common method of computing total digestible nutrients, the unavoidable loss of energy in the urine is approximately corrected. This is because digestible protein is given the same value as digestible carbohydrates. Protein actually has a considerably higher energy or fuel value than carbohydrates, but part of the energy is lost in the urine.

77. Net-energy values vs. total digestible nutrients.—There is no question but what net-energy values are theoretically more accurate than total digestible nutrients for comparing the values of roughages or low-grade concentrates with the values of the grains and other high-grade concentrates for productive purposes. This is because there is a decidedly greater loss of energy in the heat increment from each pound of digestible nutrients in the case of feeds high in fiber than with those low in fiber. Therefore each pound of total digestible nutrients in roughage or low-grade concentrates has a lower productive value than in high-grade concentrates.

Any person experienced in livestock feeding will agree that the relative value of good hay and of straw for production is far different from the amounts of total digestible nutrients in such hay and in straw. For example, average alfalfa hay has 50.7 lbs. total digestible nutrients per 100 lbs.; average grass hay, 44 to 47 lbs.; and oat straw, 44.8 lbs. No experienced stockman believes that oat straw is really worth over four-fifths as much as good alfalfa hay, or nearly as much as average grass hay, for stock being fed for production.

Unfortunately, there are decided limitations in the use of net-energy values. First of all, on account of the great cost of such investigations, the values of but very few feeds have been actually determined by experiments with a respiration calorimeter or a respiration apparatus. For example, though most such studies have been with fattening steers, the net-energy values of less than 20 feeds have been directly determined for this class of stock. The net-energy values for other feeds must therefore be estimated from the best data available.

78. Factors affecting net-energy values.—It has been pointed out previously in this chapter and is explained further in the next chapter that the digestibility of any feed varies somewhat, being influenced by several factors. **(101–106)** It is therefore necessary to average together the results of several well-conducted digestion trials to have a reliable basis for computing the average amounts of digestible nutrients supplied by any feed.

Net-energy values are considerably more variable than total digestible nutrients. First of all, there is apt to be a greater difference in the results secured with individual animals of the same kind and kept under the same conditions.[21] This may be due to the complexity of net-energy investigations.

The net-energy value of the same feed or of the same ration is also affected by the amount of feed that is given the animal. When an animal is scantily fed, the net-energy value of the ration per pound may be 20 per cent higher than when the animal is fed liberally.[22] It is pointed out in the next chapter that the amount of feed eaten also affects the digestibility of a ration, but to a much less degree.

Any nutritive deficiency in a ration may seriously reduce its net-energy value, especially if the deficiency is long continued. The effect is apt to be greater than the effect upon digestibility. In experiments by Forbes and associates a deficiency in the amount or quality of protein, or a deficiency of fat, of minerals, of thiamine, or of riboflavin decreased the net-energy values of rations for rats used as test animals.[23]

It has been found that the same feeds have decidedly different net-energy values for some classes of stock than for others. Thus, the net-energy value of a ration for mere body maintenance or for milk production was 23 to 24 per cent higher than for the fattening of cattle.[24] For swine or poultry the net-energy val-

ues of such high-grade concentrates as the cereal grains are much higher than for fattening cattle.[25] On the other hand, because swine and poultry have little ability to digest fiber, feeds high in fiber have very low net-energy values for them.

The net-energy values of high-grade concentrates are much higher for horses than for fattening cattle.[26] However, hay has a much lower net-energy value for work horses than for cattle, and wheat straw actually has a negative value. In other words, the more straw the horse eats, the less work he can do.

In addition to the effect of all of these factors, the net-energy value of a feed may be affected by the particular combination of feeds with which it is fed, even though all of the rations are balanced in protein and other nutrients. As is pointed out in the next chapter, scientists differ in their opinions concerning the importance of such "associative action" of feeds. (**104**)

79. Net-energy values in Appendix Table II.—In spite of these limitations of net-energy values, the author believes that it is possible to evaluate the most important feeds more correctly on the net-energy basis than by using the values for total digestible nutrients. He has therefore computed estimated net-energy values for the most important feeds, which are presented in Appendix Table II. These values are based upon studies of all the available data that provide information concerning the relative values of these feeds for productive purposes. The reader can decide whether to use the total-digestible-nutrient values in Appendix Table I or these estimated net-energy values in Appendix Table II. The author has endeavored to make both tables as useful and reliable as possible.

In computing the estimated net-energy values in Appendix Table II, chief reliance has been placed on the results of the hundreds of feeding experiments conducted by the experiment stations to compare the values of different feeds for fattening cattle and sheep, for dairy cows, and for swine. The other sources of data used in the preparation of this table are stated in the paragraphs that precede the table.

The net-energy values in Appendix Table II are primarily for growing and fattening livestock. As has been mentioned previously, the various feeding stuffs have higher net-energy values for milk production than for the fattening of animals. However, the *relative* net-energy values of different feeds for milk production and for fattening are probably not far different in most cases. Also, in the case of feeds which seem to have different relative values for dairy cows than for fattening stock, separate values are given for dairy cows.

Therefore, those desiring to compute rations for dairy cows on the net-energy basis can safely employ these net-energy values, using the figures for net-energy requirements given in Appendix Table III, which are designed for use with these net-energy values. These values can also be used in computing rations for work animals.

These net-energy values should not be used in computing rations for merely maintaining animals during cold weather. It is much more accurate to use for this purpose the total-digestible-nutrient values in Appendix Table I.

80. Roughages compared with concentrates.—An inspection of Appendix Table II will show that there is a considerably greater difference between the net-energy value of a high-grade concentrate and that of a dry roughage than there is between the percentages of total digestible nutrients furnished by the same feeds. For example, dent corn of Grade No. 1 supplies 81.9 therms of net-energy per 100 lbs., while timothy hay (all analyses) furnishes but 37.3 therms, or only 46 per cent as much. However, timothy hay has 60 per cent as much total digestible nutrients as does corn grain. It has 49.1 per cent total digestible nutrients, in comparison with 81.9 per cent for No. 1 dent corn.

In the case of lower-grade roughages, such as corn stover and straw, the difference between the valuations of feeds by these two systems is even greater. For instance, wheat straw has

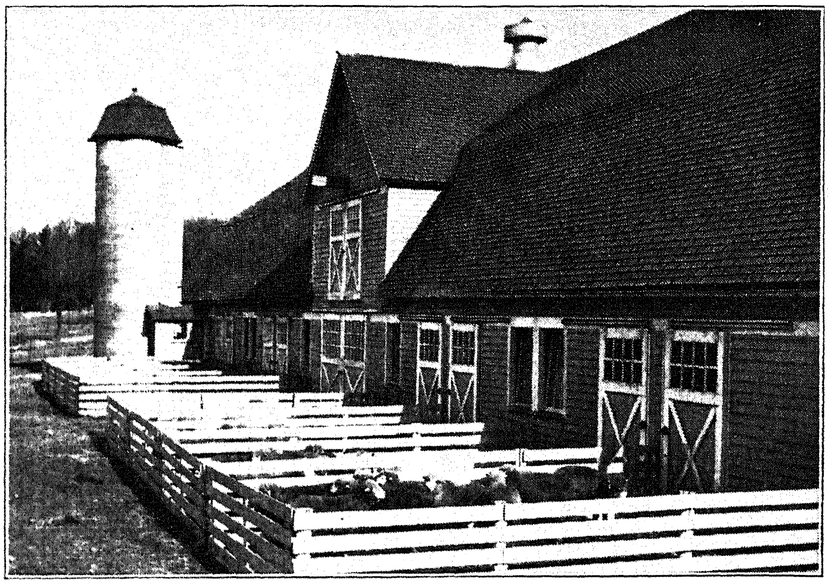
40.6 per cent total digestible nutrients, which is nearly one-half as much as dent corn. However, the straw furnishes only 10.0 therms of net energy per 100 lbs., or but one-eighth as much as does corn grain.

The reason why the net-energy values of roughages are much lower than their total digestible nutrient values has been stated previously in this chapter. It is chiefly because the losses of energy in the heat increment, or the so-called "work of digestion," are much greater in the case of feeds high in fiber than with the grains and other concentrates that are low in fiber and therefore readily digested. Therefore, when one wishes to compare the value of a roughage for productive purposes with that of a concentrate, it is more accurate to use net-energy values than to base the comparison on total digestible nutrients.

81. Determining net-energy values by feeding experiments.—It has been pointed out previously in this chapter that net-energy determinations with large farm animals are so time-consuming and expensive that such values have been obtained experimentally for very few feeds. Even for these feeds, the values were determined with only a few individual animals.

The author therefore proposed a method by which approximate net-energy values, or production values, for various feeds can be determined rather easily, by making certain modifications in the usual type of feeding experiment.[27] In this method other feeds can be compared with corn grain as a standard, since reliable net-energy values for corn have been determined in energy investigations.

To illustrate the method, let us suppose that we wish to find the approximate net-energy value, or production value, of alfalfa hay for fattening lambs, in comparison with that of corn grain. One experimental lot of lambs is fed under regular feed-lot conditions a limited amount of corn grain with a very liberal amount of hay, but no more hay than the lambs will clean up with little waste.



NET-ENERGY VALUES CAN BE FOUND IN FEEDING TRIALS

Experimental sheep barn at Cornell University where feeding experiments to determine the approximate net-energy values of various feeds have been conducted.

Another lot of similar lambs is fed considerably less hay per day. In addition, they are fed *just enough corn* to make the same gain in liveweight as is made by the lambs in the first lot. At the end of the experiment when the lambs are ready for market, the production of both lots will have been equal, so far as gain in weight is concerned. Taking the well-established net-energy value of corn grain as the standard, the approximate net-energy value of the alfalfa hay can be then computed from the amounts of corn and hay required by the two lots to produce the same gain in weight.

By careful slaughter tests it can be determined whether there is any observable difference in fatness of the carcasses of the lambs fed the two rations. If such a difference is found, a correction can be applied to the estimated net-energy value of the hay, to correct for the difference in energy value of the gain made on the two rations. This correction can be based upon data which are available concerning the energy content of the carcasses of animals of various degrees of fatness. Except for the great expense involved, it would be preferable to make chemical analyses of the carcasses of all of the lambs.

Because the method is simple and not very expensive, experiments can readily be repeated a sufficient number of times and with enough animals to eliminate most of the variations due to individuality of animals or to differences in composition of the same kind of feed. Also, since such experiments can be conducted under practical conditions, they should furnish more reliable information than we have at present concerning the productive values of most feeds.

This method has been used by the author and associates at the New York (Cornell) Station and by other investigators at the Colorado, Maryland, Michigan, and Oklahoma Stations.[28] It is suitable for use with dairy cows, as well as with fattening or growing animals.

82. Starch values.—Kellner, who conducted extensive investigations many years ago in Germany with steers in a respiration apparatus, measured the values of feeds for productive purposes in terms of *starch values,* instead of net-energy values stated in therms.[29] In this system 1 lb. of digestible starch is taken as the net-energy unit. The net-energy value of any feeding stuff is expressed as the number of pounds of starch which is believed to have the same net-energy value for productive purposes. Thus, the starch value of dent corn, according to the Kellner method, is 81.5 lbs. starch equivalent per 100 lbs.

Kellner also prepared feeding standards based on digestible true protein and starch values. These were a decided improvement over the old Wolff-Lehmann standards and were therefore widely adopted in Europe. Because of the great advance in our knowledge about animal nutrition since then, the Kellner values should now be considered as of only historical importance.

83. Armsby net-energy values.—From factors based on his net-energy investigations with steers and on the experiments of Kellner, Armsby computed net-energy values for a considerable list of feeds. These were published in 1917 in his book, *The Nutrition of Farm Animals.*

Since the net-energy values of only a very few feeds had actually been determined, most of his values were computed from the table of digestible nutrients in the fifteenth edition of *Feeds and Feeding* with the permission of the writer. Unfortunately, his method of computation was faulty, and as a result some of his values were decidely incorrect.

For example, the value of barley for all fattening ainmals is definitely lower than that of corn. Yet, Armsby's net-energy value per 100 lbs. was 89.94 therms for barley, in comparison with only 85.50 therms for dent corn. This was due primarily to the fact that in Armsby's method of computation corn was given no credit for the fact that it has twice as much fat as barley. Similarly, soybeans, flax seed, and other fat-rich feeds were given lower energy values than barley or wheat, while the values should have been much higher than for these grains.

Fully as important as these differences was the fact that lower net-energy values were assigned to all the legume hays than to timothy hay and other grass hay. For example, a net-energy value of only 34.23 therms was given for average alfalfa hay, while the value for average timothy hay was 43.02 therms. Red top hay, a grass hay

which is usually of rather poor quality, was given a value of 51.22 therms.

The Armsby net-energy values or the Kellner starch values have never been widely used in this country. This is probably because their limitations have been realized more clearly than in some other countries. The author believes that the Armsby values, like the Kellner starch values, should now be considered as having only historical importance.

84. Scandinavian feed-unit system.—The Scandinavian feed-unit system of valuing feeds is widely used in the Scandinavian countries for measuring the relative values of different feeds.[30] In this system the value of 1 lb. of barley grain is taken as the standard.

The feed-unit value for any other feed is the amount of that feed which is estimated to have the same productive value as 1.00 lb. of barley. For example, the feed unit values of soybean oil meal and of cottonseed meal for dairy cows are given as 0.85 lb. and the value of corn grain as 0.95 lb. This means that according to the estimate, it takes 0.85 lb. of soybean oil meal or cottonseed meal, or 0.95 lb. of corn, to equal 1.00 lb. of barley in feeding value.

The feed-unit values are not true expressions of net energy, for in this system feeds rich in protein are given higher values than feeds low in protein which actually furnish the same amount of net energy. The high value given to protein in the feed-unit system is undoubtedly the result of the character of the rations employed in the experiments. In the Scandinavian countries there is a shortage of protein in the home-grown feeds, and considerable amounts of protein supplements are imported. Therefore, the common rations are often rather low in protein. When added to rations which are somewhat too low in protein content, 1.0 lb. of a protein supplement naturally had a higher productive value than 1.0 lb. of barley.

The conditions in the various parts of the United States differ much more than in the Scandinavian countries. In the corn belt there is commonly a shortage of protein in the farm-grown feeds. On the other hand, in the alfalfa districts of the West, the shortage is often one of carbohydrates, and not of protein. Similarly, in the cotton belt of the South cottonseed meal is sometimes cheaper per ton than grain. Under these latter conditions, protein-rich feeds obviously do not have higher feeding values than correspond to the amounts of net energy or of total digestible nutrients that they provide. Probably because of these conditions, the feed-unit system has never been used widely in the United States.

85. Möllgaard's values.—Möllgaard conducted extensive respiration studies with dairy cows in Denmark and published feed units for milk production, or production units, of a somewhat different kind.[31] For feeds for which values have not been determined experimentally, values were computed from Kellner's starch values, or from the content of digestible nutrients. In his values recognition is given to the fact that the net-energy values of feeds are higher for milk production than for fattening animals.

86. Fraps' production values.—From extensive studies of the results of feeding experiments in which various feeds were compared, Fraps of the Texas Station computed net-energy values expressed in therms for a considerable list of feeds.[32] He called these values productive-energy values.

Fraps' values seem to be much more accurate estimates of the values of different feeds for productive purposes than Kellner's starch values or Armsby's net-energy values. For this reason considerable use was made of the Fraps' values in preparing the estimated net-energy values in Appendix Table II of this volume.

Fraps also determined net-energy values of various feeds for chicks by the method mentioned previously. (72)

QUESTIONS

1. Show, by examples, why the information gained by extensive feeding experiments is the most reliable method of estimating the relative value of different feeding stuffs for the various classes of stock.
2. Define *digestion coefficient*. How are the digestion coefficients determined directly, and also by difference, in digestion trials?
3. What is the relative digestibility of feeds low in fiber and of those high in fiber?
4. Define *total digestible nutrients*. State how the amount of total digestible nutrients is computed.
5. Define *nutritive ratio* and show how it is computed. What is meant by the term *narrow nutritive ratio;* the term *wide nutritive ratio?*
6. State three other methods for determining digestibility.
7. What 3 losses of food energy are not deducted in determining the amount of digestible nutrients in a feed?
8. Define the *net-energy value* of a feed.

For what purposes may net energy be used in the body?

9. In what terms are net-energy values generally expressed in the United States?
10. Describe a respiration apparatus. How does a respiration calorimeter differ from a respiration apparatus?
11. By what other means can net-energy values be determined?
12. Why are net energy values more accurate than total digestible nutrients for comparing the values of roughages and of concentrates for productive purposes?
13. Why may considerable straw be fed advantageously to an idle horse, but not to one at hard work?
14. Why does not the net-energy value of a roughage measure its value for maintaining stock in the winter in most sections of the United States? On what basis should maintenance rations for such animals be computed?
15. Discuss the factors which affect net-energy values. Consider (a) amount of feed; (b) nutritive deficiencies; (c) kind of animal.
16. How can approximate net-energy values be determined by feeding experiments?

CHAPTER IV

FACTORS AFFECTING THE VALUE OF FEEDS

I. The Preparation of Feeds

87. When does preparation of feed increase its value?—It is of much financial advantage to stockmen to know whether or not any particular method of preparing feed for farm animals is profitable. Extravagant advertising claims are sometimes made concerning the supposed savings that will result from a certain method of preparing feed. It is therefore highly important that a farmer have reliable information on this subject, before spending money for equipment.

It is often assumed that by grinding or chopping feed much labor is saved the animal and that the value of the feed is therefore increased decidedly. This idea is based on the supposition that the less work the animal does in mastication and digestion, the greater will be the amount of nutrients left for useful production.

However, this is apparently not true. Making feeds so fine and soft that they can be swallowed with little chewing, not only fails to pay for the cost of such preparation, but it may actually lower the value of the feed.

The value of grinding, crushing, or chopping feed depends on the character of the particular feed in question and also on the kind of animal to which it is to be fed. Therefore the economy of these methods of preparing feed for each class of stock is considered in detail in later chapters. In this chapter there are discussed only certain general principles that apply to the various classes of feeding stuffs and to the different kinds of livestock.

In some cases, feeds that are unpalatable to stock will be consumed readily if they are ground and mixed with those that are well liked. For example, rye gives better results with most classes of stock if it is mixed with more palatable grains.

To induce animals that are being fitted for show to consume a little more feed than they might otherwise, the grinding of grain, the chopping of hay, or the soaking of feed may sometimes be helpful, even though the expense of such preparation would not be justified for other stock. There will naturally be more saving in grinding feed for animals with poor teeth than for those that can chew their food normally.

88. Grinding grain or other seeds.—In the case of grain or other seeds, grinding, crushing, or soaking is usually profitable only when the particular animals fail to chew the seeds thoroughly. Seeds that escape chewing may pass through the digestive tract without appreciable digestion, and thus the nutrients are lost. Whether or not it will pay to grind grain for any class of stock is therefore a problem that can be determined only by actual feeding experiments with that class of animals.

Such preparation may be advisable for very young animals, before their teeth are well developed, but later it may not be beneficial. Also, in certain instances animals chew their feed less thoroughly as they grow older, and the grinding of grain is then advisable, even though it may not have been worth while for the same animals when somewhat younger.

For example, after they are a few weeks old, calves chew corn or oats thoroughly up to about 6 or 9 months of age, and there is hence no advantage in grinding these grains for them. After this age, it usually pays to grind the grains. Similarly, growing and fattening pigs chew corn with such thoroughness up to the usual market weights, that it does not generally pay to grind it for

them. However, older pigs chew corn less thoroughly, and therefore the saving through grinding is greater.

All grains should commonly be ground for dairy cows. Grain should also be ground for beef cattle, with the exception that it does not pay to grind corn for them if pigs follow the cattle to salvage the unchewed corn kernels in the manure. All grains except corn and oats should be ground or crushed for horses and mules. In general, sheep chew their feed the most efficiently of all the larger farm animals. As a result, there is generally no advantage in grinding grain or other seeds for them, except in the case of seeds that are unusually small or hard.

89. Fineness of grinding.—Grain should not be ground so fine that it is dusty and floury, but instead it should be ground only medium fine. Extremely fine grinding not only takes much more power and time, but it generally makes the grain less palatable and may actually reduce its feeding value.

In various experiments it has required only one-half as much power and sometimes even less, to grind grain to a medium fineness as to grind it into a fine floury meal.[1] It is shown in later chapters that in experiments with dairy cows, lambs, pigs, and hens, grain ground medium-fine has also had a higher feeding value than that ground more finely.

The cost of grinding is somewhat less when grain is merely cracked than when it is ground to a medium degree of fineness. However, the utilization of the cracked grain is enough lower to make medium-fine grinding preferable. When grain screenings, which consist to a considerable extent of weed seeds, are fed to stock, many of the smaller seeds may pass through the digestive tract unchewed and alive. Very fine grinding of such screenings is therefore desirable to prevent infesting the fields with weeds, through applying manure that contains live weed seeds.

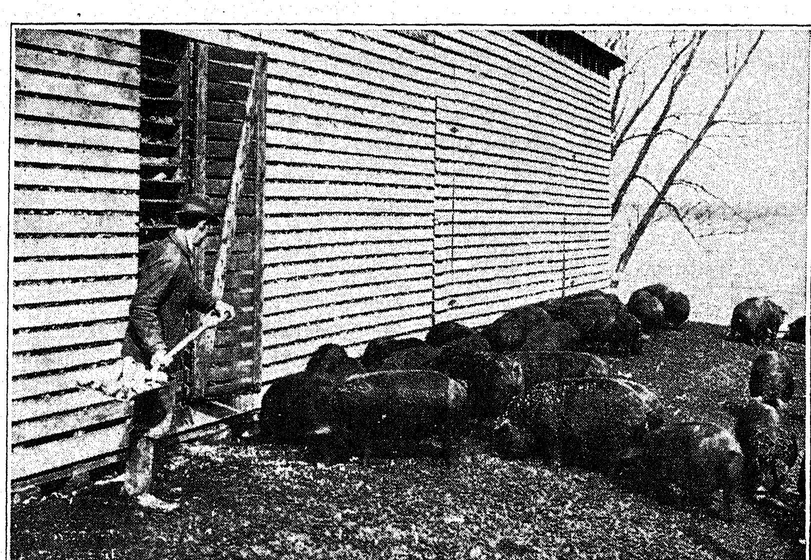
GRAIN SHOULD BE GROUND FOR DAIRY COWS

Dairy cows do not utilize whole grain efficiently, even corn and oats. It therefore pays well to grind grain for them.

90. Rolling or crushing grain.—The relative merits of rolling or crushing grain, compared with grinding it, have been much discussed. In fitting stock for

show on a full feed of concentrates, many stockmen prefer rolled or crushed grain in the mixture. This is because it is more bulky and may be less likely to cause digestive disturbances in such heavy feeding. Horsemen also often prefer rolled or crushed grain for feeding, as it is more bulky and may be less apt to cause colic.

For other classes of stock there is probably not much difference in the value of grain that has been rolled or crushed and that which has been ground.



THE SCOOP SHOVEL METHOD OF PREPARING CORN FOR PIGS

Up to the usual market weights, pigs utilize ear corn or shelled corn so efficiently that it does not pay to grind corn for them. (From Iowa Station.)

91. Pellets or cubes; crumbles.—Pellets or cubes are made by special machines from mixtures of concentrates or of concentrates and ground roughages, using pressure, usually with the addition of steam. Alfalfa meal is often pelleted to reduce bulk and expense in shipment. Sometimes pelleted feeds are broken coarsely by machine to form "crumbles." Much interest is currently being shown in hay pellets or "wafers." Such uses are discussed in the chapters dealing with the various classes of stock.

Pelleted feeds are especially adapted for outdoor feeding and for use as supplements for stock on pasture or range, as there is less wastage from wind and weather than when a ground mixture is fed. Since a certain weight of feed takes up less space when pelleted, animals may eat more feed in pelleted form than if the same mixture is fed ground.

Probably for this reason, broilers and young turkeys fed pellets may gain more rapidly and more efficiently than if fed the same mixture in mash form. The results have differed in the trials in which pellets have been compared with mash feeding for laying hens.

Growing and fattening pigs may gain appreciably faster and require less feed per 100 lbs. gain when self-fed a pelleted ration than when fed the same mixture as meal. The difference is greater when there is a large proportion of barley or oats in the mixture, than when corn, which is more concentrated, is the chief grain.

Several experiments have been conducted with fattening lambs to compare self-feeding a pelleted mixture of concentrates and ground hay with self-

feeding or hand-feeding the same kind of ration. Considering all trials so far conducted, feed consumption increased while both gains and feed efficiency improved. The increase in feed intake is largely responsible for the results. With cattle, more variable and less dramatic responses are usually observed. If roughage is of poor quality, pelleting gives better gains than if of good quality. A higher incidence of ruminal parakeratosis has been noted in lambs fed all-pelleted rations.

The cost of pelleted feed compared with ordinary rations largely determines the economy of this method of feeding.

Experiments have shown that a pelleted or coarse-textured concentrate mixture is no better for dairy cows than a mixture of ordinary fineness. (**1052**)

92. Chopping or grinding hay or other roughage.—In the case of hay, stover, and straw, there are no hard seed coats to be broken. Consequently, the ordinary chewing by livestock tears the forage into particles that can readily be penetrated by the digestive juices. Additional expense for chopping or grinding such roughage is therefore usually advisable only if it induces animals to eat coarse, stemmy portions that they would otherwise waste; or if they will consume a greater total amount of the roughage than when fed without the preparation.

For cattle, sheep, or horses, chopped hay is decidedly preferable to ground hay, and coarsely chopped hay is better than hay chopped fine. Not only are much less time and power required to chop hay than to grind it, but also chopped hay is much more desirable. Ground hay is apt to be less palatable to stock, and it is often so dusty that it is disagreeable to handle. In addition, the fine grinding of hay does not increase its digestibility, and may even decrease it.[2]

It is shown later that where a sufficiently large acreage of hay is made on a farm, handling it with a forage harvester, or hay chopper, is a very economical method. (**407**) By this means, hay may often be stored at no greater expense than for long hay. In chopping the hay, the machine should be set so as to chop the hay into as long lengths as is possible.[3]

In general, for dairy cows, beef cattle, sheep, and horses, it does not pay to go to extra expense to chop hay that is of good enough quality to be consumed with but little waste when fed long. If long hay is not fed in mangers that prevent undue waste, there may be considerable saving in chopping it. For example, in the West fattening lambs are commonly fed in open lots, and the alfalfa hay is frequently put on the ground, simply being rolled up against the fence of the feedlot. Under such conditions there is considerable wastage, and therefore chopping the hay and feeding it in a suitable rack or self-feeder makes a sufficient saving to justify the expense.

If hay is coarse and stemmy or otherwise of poor quality, there may be more advantage from chopping than with hay of good quality. Not only will the wastage be reduced, but also the stock will usually eat a greater amount of such roughage if it is chopped.

If one has an abundance of hay but it is of rather poor quality, it may be best not to chop it for dairy cows or for fattening cattle or sheep, but to feed very liberal amounts of the uncut hay. The stock can then eat the finer and more nutritious parts and leave the coarse stems, which have a very low feeding value. The stems can be used for bedding, or else given to animals that are not being fed for production, such as stock cattle being carried through the winter for fattening later, or to idle horses. It must be borne in mind that the chopping or grinding of roughage does not change the chemical composition of the stemmy portion at all, nor convert it into a high-grade feed.

In the case of corn or sorghum stover, it usually pays to cut or shred it to lessen the refuse, and also because the waste is then much better for bedding. Cut, shredded, or ground stover or fodder will heat or mold in storage unless thoroughly dry. For this reason, in humid districts such roughages frequently can-

not be kept for more than a few days, even in cool weather.

93. Mixing chopped or ground roughage with concentrates.—Claims have often been made that the value of a ration will be greatly increased if the roughage is chopped or ground and mixed with the grain or other concentrates. In spite of these claims, experiments have shown that such mixing of the feed does not generally increase its digestibility or its nutritive value. Farm animals have digestive systems which mix very thoroughly the feeds they eat.

However, in special cases the mixing of roughage with grain may be desirable from other standpoints. For example, horses are apt to have colic if fed a heavy grain, such as ground wheat or barley, as the only concentrate. Mixing with the ground grain a small proportion of a bulky feed, such as chopped or ground hay, ground oats, or wheat bran, will largely prevent the trouble. Fattening lambs which are self-fed a heavy feed, like corn, often suffer from digestive troubles. Mixing chopped or ground hay or some other bulky feed with the grain aids in preventing such difficulties.

It is highly desirable, when pigs are not on pasture, that they get some legume hay to provide vitamins A and D. If legume hay, even of good quality, is fed uncut in a rack, young pigs will frequently eat but little of it. It is therefore advisable to mix 5 per cent or more of chopped or ground legume hay in their concentrate mixture in order to force them to eat it.

Ground alfalfa meal or alfalfa leaf meal is also commonly included in poultry mashes as a vitamin supplement.

94. Cooking feed; soaking feed; feeding slop.—Many years ago it was firmly believed that cooking or steaming feed greatly increased its value. Careful experiments showed, however, that except in the case of the very few feeds mentioned later, such preparation does not increase the digestibility or feeding value. Instead there is a loss in most instances.

The only exceptions are a few feeds, especially potatoes, field beans, and soybeans, which are much better for feeding swine or poultry when the feeds are cooked. Soybean oil meal that has been properly cooked in the manufacturing process is also much superior to raw-tasting soybean oil meal for swine or poultry.

When grain with small or hard kernels cannot conveniently be ground or crushed, it may be advisable to soften it by soaking before feeding. Care should then be taken that such soaked grain does not become stale by long standing. Old corn often gets hard and flinty in summer and sometimes causes sore mouths in cattle or other stock if fed whole. It should then be ground or soaked.

Many farmers still feed ground grain and other meals to their hogs in the form of slop, believing that slop-feeding produces much better results than dry-feeding. However just as satisfactory results are generally secured when the same feeds are given dry, and much labor and bother are saved.

95. Fermenting, pre-digesting, malting, or sprouting feeds.—From time to time various processes of fermenting, malting, or pre-digesting feeds have been exploited by clever promoters. Claims have been made that these processes would save one-third to one-half the feed usually supplied livestock and would result in better production. Careful experiments have shown that these expensive methods of feed preparation do not cause any saving in feed or result in greater production.[4]

Some years ago, a method of sprouting grain for stock was advertised with extravagant claims of a great increase in feeding value. However, experiments showed that instead of a gain, there was a loss of 25 per cent of dry matter in the process.[5] Sprouted oats, which have sometimes been recommended as a cure for sterility in cattle, have not generally proven beneficial.

In Europe, methods of treating straw with caustic alkali to make it more digestible have sometimes been used during shortages of other feed. (**626**)

II. Factors Influencing the Nutritive Value of Feeds

96. Variations in the composition of feeds.—In computing rations for livestock, it is important to know how much the actual composition of any particular lot of a given feed may vary from the average given in Appendix Table I of this volume or in similar tables.

The following summary shows that the average figures for the composition of any feeding stuff are but approximately correct when applied to a particular lot of the feed. This is also true of any expression of its nutritive value, whether stated in terms of digestible nutrients or of net energy. In other words, different lots of any feed vary in feeding value, the same as different samples of coal vary in fuel value.

Owing to the expense of obtaining chemical analyses, it is out of the question for any but the most extensive feeders to have their particular feeds analyzed. With the cereals and the roughages most stockmen must therefore rely on that average given in tables of digestible nutrients or of net energy values which corresponds most closely in his judgment to the feed at hand.

In purchasing commercial concentrates it is now fortunately possible in most sections of the country to secure standard brands, whose composition is fully guaranteed by the manufacturer.

97. Differences in water content.—Obviously, the amount of moisture in grain or any other feed directly affects its nutrient content. Of the cereals, corn commonly varies most in water content. Therefore separate averages are given in Appendix Table I for dent corn of the various Federal grades, which are based largely on the water content.

Such roughages as corn fodder, corn stover, sorghum fodder, and sorghum stover also vary widely in water. For example, analyses of corn fodder and corn stover show a water content ranging from over 50 per cent in field-cured material in wet seasons, down to 10 per cent or less in arid regions, or when cured under cover in a dry season. Corn fodder having only 10 per cent of water supplies 80 per cent more nutrients per 100 lbs. than does corn fodder that contains 50 per cent of water! Separate averages are therefore given for very dry and for ordinary field-cured samples of these feeds in Appendix Table I.

98. Differences in roughage composition.—Roughages vary much more than most concentrates in composition. Their nutrient content may be greatly affected by the stage of maturity; the water content; the amount of plant food in the soil, especially phosphorus, nitrogen, and calcium; and in the case of hay or other cured forage, by weathering, shattering of the leaves, or leaching during curing.

On account of the great differences in the composition of the same variety of hay or other forage, separate averages are given in Appendix Table I for the various grades or qualities of the most important roughages, wherever sufficient data are available. The effects of various factors on the composition and feeding value of pasturage and hay are discussed in some detail in Chapters XIII and XIV.

It is there pointed out that there may be more actual difference in the feeding value of two lots of the same variety of hay than there is between hay of two entirely different kinds. For example, two loads of alfalfa hay may differ more in value than a load of alfalfa hay and another of timothy hay.

The supply of mineral nutrients in the soil not only affects the yield of crops, but also in the case of forages it may have very important effects on composition and nutritive value.[6] Also, proper fertilization may make pasture or hay more palatable to stock.[7] When only certain strips in a poor pasture are fertilized, stock will usually graze down the fertilized strips before they eat the rest of the forage. This may chiefly be because the fertilized plants are larger and more succulent.

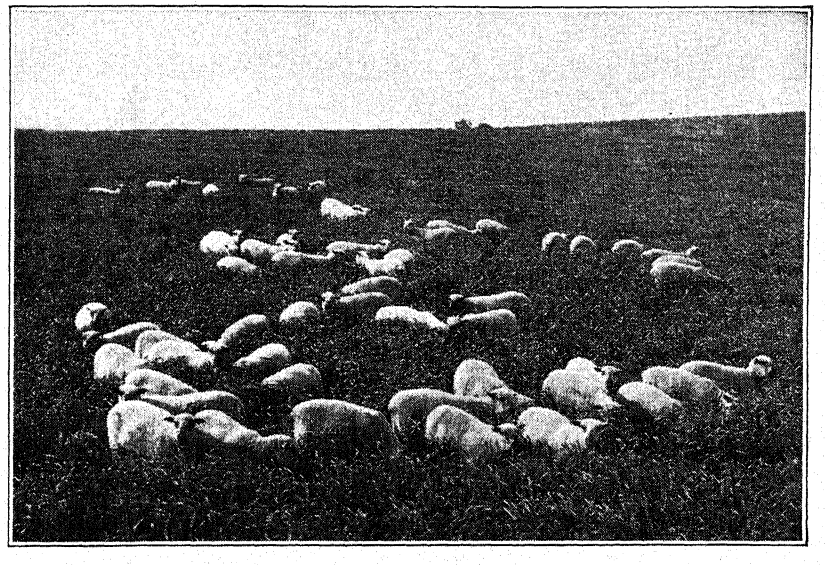
Pasturage or other forage grown on soil decidedly deficient in phosphorus is generally very low in phosphorus. Such forage may produce a serious deficiency in livestock, unless the animals are sup-

plied with a phosphorus supplement. The application of a phosphorus fertilizer to such soils will not only greatly increase the yield of forage, but it will also generally bring the phosphorus content of the forage up to normal levels.[8]

Deficiencies of calcium in forage crops are much less apt to occur than lacks of phosphorus. Even when grown on soil low in calcium, legume forage crops seem always to have a good content of calcium, though the yield may be greatly decreased by the lack of this mineral nutrient. However, the percentage of calcium in legume forage is generally higher when grown on calcium-rich soil than when raised on land deficient in calcium. The calcium content of non-legume forages is usually considerably less on calcium-poor soil than on soil containing plenty of calcium.

In a few areas the soil is so deficient in cobalt, copper, or iodine that very serious nutritional diseases are produced in livestock because of a lack of one or more of these "trace elements" in the forage. Such troubles can be prevented by the feeding of a mineral supplement, as explained in Chapter VI.

Where there is a border-line deficiency in the soil of cobalt or another trace mineral nutrient, liberal fertilization with ordinary fertilizers is apt to decrease the trace mineral content in the forage.[9] This is because the available amount of trace mineral is diluted in the much greater amount of forage produced.



ROUGHAGES VARY GREATLY IN COMPOSITION

The composition of a forage crop is greatly affected by the stage of maturity and also by the soil fertility. Young small-grain pasture, such as this, is rich in protein, on the dry basis, but hay made from small grains is relatively low in protein.

On soil very deficient in sulfur, fertilization with sulfur will not only greatly increase the yield of alfalfa and other legumes, but it will also improve the sulfur content and the feeding value of the forage.[10]

The protein content of forage crops is affected much more by the stage of maturity than by the supply of nitrogen in the soil. (359) At immature stages of growth most forage crops are much richer in protein than when more mature. Proper fertilization of pasture or hay land may greatly raise the protein content of the forage, because it increases the proportion of clovers or other leg-

umes. Also, liberal fertilization with nitrogen not only decidedly increases the yield of grasses on nitrogen-poor soil, but also improves the protein content. (372)

The increase in protein of grasses is greatest when nitrogen fertilizer is applied not only early in the spring but also later in the season. On soil low in nitrogen, liberal fertilization with nitrogen greatly increases the yield of corn and also improves the protein content of both the forage and the grain.[11]

It is fortunate indeed that proper fertilization not only increases the yield of pasture and other forage crops, but may also very decidedly improve the nutritive value. (383)

99. Differences in composition of grains and other seeds.—Climate and crop variety are the most important factors influencing the composition of the grains and other seeds. The yield of seeds may be greatly lowered because of a lack of plant food in the soil, but the percentage composition of the seeds is affected much less than with forage crops. Thus, a deficiency of phosphorus in the soil will reduce the percentage of phosphorus in grain much less than in forage crops.

It is pointed out in Chapter XX that the varieties of hybrid corn commonly grown are definitely lower in protein than the open-pollinated varieties grown some years ago. (682) This is apparently due both to inherited difference in protein content and to the greatly increased yield of hybrid corn. Unless hybrid corn is amply fertilized with nitrogen, the percentage of protein in the large yield of grain is lowered by a lack of nitrogen.

It is shown in Chapter XX that there is a wide variation in the percentage of hulls in oats, and therefore in the fiber content and the feeding value of the grain. Oats with shrunken kernels may be fully one-half hulls, while there should not be over 30 per cent of hulls in grain of good quality. Barley also varies in percentage of hulls, though not so much as does oats.

The protein content of wheat, oats, or barley is affected very materially by climate, and to a much smaller extent by the variety and other factors. It is pointed out in Chapters XX and XXI that these grains are especially low in protein when grown in certain districts of the Pacific Coast region. Separate averages are therefore given in Appendix Table I for these grains from that section of the country. The protein content of wheat may be appreciably increased by liberal fertilization with nitrogen.[12]

The composition of corn grain is affected by climate much less than that of the small grains, provided the crop matures. Fraps showed that under Texas conditions in seasons with abundant rainfall from January to June, the protein content of corn is apt to be slightly less than in dry seasons.[13]

Samples of the same variety of corn and wheat from the same region may vary 10 per cent and sometimes even more in content of protein or fat. There are much larger differences in the composition of different varieties of corn and wheat.

The nitrogen-free extract is less variable than the protein or the fat.

100. Differences in composition of by-product feeds.—Separate averages are given in Appendix Table I for the various grades of all important by-product feeds which vary to any marked extent in composition. Thus, averages are given for cottonseed meal, linseed meal, soybean oil meal, peanut oil meal, etc., containing various percentages of protein.

In accordance with the feeding-stuffs laws in the various states, the by-product feeds are sold with definite protein, fat, and fiber guarantees. (31) By comparing the guarantees for any lot of feed with the averages in Appendix Table I, one can find the approximate composition and the content of digestible nutrients in the feed. Feeds made by reliable manufacturers will usually have slightly more protein and fat and a little less fiber than stated in the guarantee. This practice is followed as insurance against any particular lot of the feed falling below the guarantee in protein or fat or coming above the guarantee in fiber.

Unfortunately, certain grades of meat scrap, tankage, and cottonseed meal seem commonly to have slightly less protein than is guaranteed by the manufacturer. (Appendix Table I)

In general, by-product feeds sold with a definite guarantee of composition will tend to vary decidedly less from the average for the particular grade of the feed than do the grains or the common roughages.

101. Effect of amount of feed eaten.—Experiments have shown that farm animals usually digest a slightly larger percentage of their feed when fed a scanty ration than when they receive a full ration that includes a liberal allowance of concentrates. Also, there is even a greater difference in the percentage utilization in the body of the nutrients from scanty and liberal rations.

When the ration contains a considerable proportion of roughage, the difference in digestibility of a liberal and a scanty ration is not large. In tests with cattle and sheep, from 3 to 9.5 per cent more of the dry matter in a mixture of roughage and concentrates was digested when the animals were fed only enough for maintenance than when they were fed liberally.[14] When fed hay alone or such a combination as hay and roots, ruminants may digest a full feed as completely as a scanty ration.[15]

It might seem at first that the feeding of a scanty ration would result in more efficient production. However, an animal can use for the production of meat, milk, or work only the nutrients consumed in excess of the amount needed for the maintenance of its body. Therefore, if it is fed scantily, it will have available for production only a small proportion of the total feed eaten.

For example, a good dairy cow that is well fed needs about one-half her feed merely to maintain her body. She uses the remaining one-half for milk production. If she is fed only two-thirds as much feed, she will digest the scanty ration somewhat better, but she will still need about as much feed as before to maintain her body. Therefore she will probably have available for milk production only 30 per cent or less of the total feed she eats. It is of great importance in practical stock feeding that this factor usually more than offsets the increased digestibility and percentage utilization of a scanty ration.

Even if a slight reduction from full feeding causes a trifle better percentage utilization of the ration, other factors usually make liberal feeding more profitable. Just as in the case of a factory which is run below its normal capacity, the overhead costs in stock feeding are greater when an animal is producing at a low rate. For example, the expense per pound of product for labor, for housing, and for interest on money invested are all much higher when the rate of production is low.

In certain cases it may be advisable for other economic reasons to feed animals less grain or other concentrates than normal. Thus, when grain is very high in price in comparison with hay or other roughage, fattening cattle may return the most profit if their allowance of grain is reduced and they are fed all the roughage they will eat.

Again, it may sometimes be most profitable to fatten meat animals more slowly than usual, so as to have them ready for market at a time of the year when prices are usually high. These various matters are discussed in detail in the chapters of Part III.

It is shown in Chapter XXXIV that leaner carcasses and higher-quality bacon are produced if pigs are fed during the finishing period a somewhat limited amount of feed or else a ration higher than normal in fiber.

In most of the digestion trials that have been conducted with cattle and sheep to determine the digestibility of various feeds, the animals have not been fed all they would eat. The amounts of feed have been restricted somewhat, as otherwise they might not eat all the feed that was weighed out, which would make it impossible to find the digestibility of the ration that had been fed. For this reason the average digestion coefficients given in Appendix Table I are undoubtedly slightly too high to show

the actual digestibility of feeds by liberally-fed dairy cows, fattening cattle, or fattening lambs.[13] Consequently, such stock will not secure from the various feeds quite so much digestible protein and total digestible nutrients as shown in Appendix Table I.

The differences are only slight, however, and these facts have been fully taken into consideration in the recommendations made in the Morrison feeding standards. Therefore rations for dairy cows, fattening cattle, and fattening lambs which are computed according to these standards and from the averages in Appendix Table I will be entirely satisfactory in practical livestock feeding.

102. Effect of nutritive deficiencies.—Any marked nutritive deficiency may seriously reduce the digestibility of the food. In the case of ruminants this is partly due to the fact that the cellulose-digesting bacteria in the rumen need ample supplies of nutrients for effective development and activity. As emphasized in Chapter II, cellulose digestion in ruminants is much lowered if there is a lack in the food of protein or a protein substitute, or of the essential minerals. (**45**)

Digestibility is also much reduced when a ration has too little protein in proportion to the amounts of easily digested carbohydrates. This is of great importance, for it is one of the reasons why a protein-poor ration is inefficient.

One of the reasons why ruminants digest such rations poorly is that when there is a large proportion of easily digested carbohydrates, the bacteria in the rumen attack the more readily available starch or sugars instead of the resistant cellulose. Not only is the digestibility of the fiber consequently lowered, but also that of the protein and nitrogen-free extract, for the unattacked cellulose cell walls protect the proteins and carbohydrates contained therein from the action of the digestive juices. If a sufficient amount of protein-rich feeds is added to balance the ration, the bacteria seem to be so stimulated that they attack the fiber of the food again.

The extent of this loss is shown in a compilation made by the author of the results of digestion experiments with cattle or sheep in which kafir grain was fed in properly-balanced rations and in rations too low in protein. When fed in unbalanced rations, 100 lbs. of kafir supplied only 58 per cent as much digestible protein and 57 per cent as much total digestible nutrients as it did when fed in a balanced ration. Similar data might be given for the other grains.

In the case of mature fattening cattle or mature work animals, the actual needs of protein for body repair or the making of new protein tissues are very small, as is explained in later chapters. However, because of this depression of digestibility, it is economical to feed such stock somewhat more protein than is needed for their theoretical requirements. These facts are fully taken into consideration in the Morrison feeding standards. (Appendix Table III.)

The depression of digestibility caused by a lack of protein occurs with ruminants when the nutritive ratio is wider than about 1 : 8 or 1 : 10, but with swine the nutritive ratio may be even wider before digestibility is affected.

The decrease in the digestibility of protein on a ration low in protein is more apparent than real. The addition of non-nitrogenous food to a ration causes a greater excretion of protein in the feces. The amount of this additional loss depends chiefly on the amount of food added. This larger excretion of protein may consist chiefly, not of undigested protein, but of protein that has been assimilated and then excreted as a waste. However, from the practical standpoint, the additional wastage of protein is just as truly a loss as though it represented solely a decrease in actual digestibility.

In conducting digestion trials to determine the digestibility of feeds that are rich in easily-digested carbohydrates, but low in protein, it is exceedingly important to add a sufficient amount of protein supplement to the ration to prevent any depression of digestibility. This is well shown in experiments by Holdaway and associates of the Virginia Station.[16] In previous digestion trials made by various investigators, the protein in apple-pomace silage, which is very low in protein and very high in easily-digested carbohydrates, was apparently not digested to any

appreciable extent. On the other hand, in the Virginia tests when a sufficient amount of protein supplement was included in the ration, along with the pomace silage, 37 per cent of the protein in the silage was digested, and the digestibility of the nitrogen-free extract was also slightly increased.

103. Effect of proportion of other nutrients.—The addition of more than a small amount of molasses or of sugars in some other form to a well balanced ration for ruminants may slightly decrease the digestibility, especially of protein.[17] This is apparently because the bacteria in the rumen tend to attack the sugar instead of the fiber and other more resistant carbohydrates in the rest of the ration. The results secured from the addition of molasses to practical rations for various classes of stock are discussed in detail in Chapter XXIII.

The addition of fat to a ration does not generally increase the digestibility of the other constituents.[18] It has been found that feeding cattle more than 1 lb. fat per 1,000 lbs. weight or feeding pure fat or oil in unemulsified form may cause digestive disturbance. The effects of different amounts of fat in rations for the various kinds of stock are discussed in later chapters.

The addition of salt to a ration does not affect digestion, even when a large amount is added.[19] The salt needs of farm animals are treated in later chapters.

In a New Hampshire experiment the addition of an excessive amount of ground limestone lowered the digestibility of silage for dairy heifers, but a normal amount did not have this effect.[20]

The addition of dilute acids, such as lactic acid (the chief acid in sour milk and in silage) or of sulfuric acid, does not influence digestibility. This is important because silage contains considerable free acid.

Adding fiber to a ration reduces the apparent digestibility of the protein, but not its actual digestibility.[21] (**102**)

104. Associative action of feeds.—In some digestion experiments certain feeds have been more digestible when fed in balanced rations with certain other feeds than when fed in other well-balanced combinations.[22] The term "associative action" has been applied to these effects.

Opinions differ as to the importance of such differences in practical stock feeding when well-balanced rations are fed, because some investigations have shown no differences of this kind, or only very slight ones.[23]

105. Effect of other factors in feed.—If green forage is cured without waste and in a manner to prevent fermentation, the mere drying does not appreciably lower its digestibility. Ordinarily, however, losses of some of the finer and more nutritious parts occur in curing forage. Also, fermentation and leaching cause changes which lower digestibility and decrease the content of nutrients. (See Chapter XIV.) Furthermore, more energy is required in masticating dry forage and passing it through the digestive tract than in the case of green forage. These facts explain why green forage is somewhat more digestible and commonly gives better results than dry forage. The long storage of fodders, even under favorable conditions, decreases both their digestibility and palatability. In the making of brown hay, as is pointed out in Chapter XIV, heavy losses of nutrients occur.

A comparison of the digestion coefficients for various kinds of silage with those for the green forages from which the silage was made, shows that ensiling tends to decrease rather than increase the digestibility. The exceedingly favorable results from silage feeding are therefore due to the palatability of the silage, to its beneficial effect on the health of the stock, and to the fact that less feed is wasted than when dry fodder is fed.

If a feed is heated to an unduly high temperature in a manufacturing process, the digestibility may be considerably decreased, especially that of the protein. The value of grain damaged by fire will depend on the extent of the damage.[24] Badly charred grain has little value, while that damaged by smoke may be nearly equal to sound grain, except in palatability.

Grain damaged by frost is usually higher in fiber than normal grain and is consequently less digestible and of somewhat lower feeding value.[25]

The digestibility of a few feeds is increased markedly by cooking, especially for swine and poultry. As is pointed out in later chapters, this is the case with beans, soybeans, and potatoes.

106. Effect of miscellaneous factors.—Cattle and sheep digest most kinds of feed equally well, but such low-grade roughages

as straws, which are very high in fiber, are digested somewhat better by cattle than by sheep.[26] In Pennsylvania experiments there was no marked or consistent difference in the digestibility of the same mixture of hay and concentrates by dairy cows and by sheep, when they were fed at a similar level above their maintenance requirements.[27]

Horses and pigs digest less fiber than do ruminants, in whose paunch the coarse feeds undergo special preparation and digestion. The richer the feed, the more nearly do the digestive powers of horses approach those of other farm animals. Swine digest concentrates fully as well as do ruminants, but make only small use of the fiber. Poultry digest fiber to a much less extent than do ruminants.

In general, age does not, in itself, influence digestibility, though young farm animals cannot utilize much roughage until their digestive tracts are developed. The digestive power of old animals is often indirectly impaired by poor teeth, which make the proper chewing of their food impossible.

Breed does not influence digestibility. Individual animals may, however, show considerable difference in their ability to digest the same ration, though ordinarily the digestibility of a given ration by different animals of the same kind will not vary by more than 3 to 4 per cent.

Neither the frequency of feeding, the time of watering, nor the amount of water drunk (within reasonable limits) appears to influence digestibility.[28] Moderate exercise tends to increase digestibility, but excessive work lowers it.[29]

The flow of saliva and the other digestive juices is checked by fright. On the other hand, kind treatment and palatability of food should favorably influence digestion. Under skillful care animals show remarkable relish for their food, and it is reasonable to conclude that better digestion results.

QUESTIONS

1. What general principles determine whether or not it will pay to grind or crush a certain kind of grain for a particular class of stock?
2. To what degree of fineness should grain ordinarily be ground for stock feeding?
3. What are pelleted or cubed feeds and when may they be advantageous?
4. Discuss the chopping of hay or other roughage for livestock; the grinding of hay or other roughage.
5. Under what conditions may it be wise to mix cut or ground roughage with concentrates?
6. Discuss the cooking of feed for cattle; for swine.
7. When would you soak feed for stock or feed slop to pigs?
8. What have experiments shown concerning any benefit from fermenting, predigesting, or malting feeds, or sprouting grain?
9. Give an example of the effect of a difference in water content on the value of a feed.
10. What factors affect the composition of roughages?
11. Discuss the effect of soil fertility and of climate on the composition of grain and other seeds.
12. Which tend to vary more in composition—by-product feeds of guaranteed composition or grains and common roughages?
13. Discuss the effect of the amount of feed eaten on its utilization. Should dairy cows or fattening stock be fed scantily, in order that they will digest their rations most completely?
14. What is the effect upon digestibility of having too little protein in a ration?

CHAPTER V

PROTEINS—FATS—CARBOHYDRATES

I. Proteins in Livestock Feeding

107. Importance of proper amount and kind of protein.—It has long been known that all animals must receive in their food at least a certain minimum *amount* of protein. More recently, investigations have shown that for man and for such animals as swine, poultry, dogs, and rats, the *quality* or *kind* of protein is fully as important as the amount. The quality of protein in rations is therefore discussed in detail in the pages that follow.

The general requirements of protein for various body functions are considered in Chapters VIII to X, and further information on the requirements of each class of stock is presented in Part III. The amounts of digestible protein advised by the author for the different classes of stock are shown in the feeding standards presented in Appendix Table III.

In estimates of the minimum amounts of protein required by farm animals, such as are given in feeding standards, it is assumed that typical rations are fed, which provide protein of average quality. If the protein is of superior quality, a somewhat smaller amount will suffice. On the contrary, if the protein is of inferior nutritive value, a greater amount will be needed, and even then the production of the animals will generally be lowered, in spite of the liberal supply of the inefficient protein.

It has been explained in Chapter I that *crude protein,* called merely *protein* generally in this book, includes all the nitrogenous compounds in feeds. (18) It is determined by finding the percentage of nitrogen and multiplying this by 6.25. (24) To distinguish the substances which are actually protein from the simpler nitrogenous compounds, the term *true protein* is used.

108. Effect of an excess of protein. Protein-rich feeds are generally more expensive than those which are low in protein but rich in carbohydrates and fat. In practical livestock feeding we are therefore commonly interested only in knowing the minimum amounts of protein that farm animals require for the best results.

However, protein-rich feeds may sometimes be cheaper than carbohydrate-rich feeds. This is often the case, for example, with cottonseed meal in the South and with alfalfa hay in certain sections of the West. The question then arises as to how much protein farm animals can be fed without injury. This problem is of especial interest because an excessive amount of protein throws an increased load on the liver and kidneys, which must excrete the surplus nitrogen.

Experiments have shown that there is no danger from feeding farm animals a considerably larger amount of protein than they actually require. As shown in Chapter XXII, dairy cows have been fed cottonseed meal, which is very rich in protein, as the only concentrate without injurious results, if they had plenty of vitamins and minerals. Pigs have made normal gains and remained in good health on rations containing 30 to 42 per cent of total protein.[1]

It is shown in Chapter II that although protein has considerably more gross energy than do carbohydrates, it does not furnish any more net energy. (73) For this reason, when a larger amount of a protein-rich supplement, such as soybean oil meal or cottonseed meal, is fed than needed to balance the ration, the excess amount is worth no more and often a little less than corn or other grain.

It was formerly believed that an excess of protein would increase the heat production in the body, and thus lower

the net energy value of an entire ration. Protein-rich diets were therefore considered unsuited for hot weather. However, in actual experiments an excess of protein has not had this effect.[2] The excess amount of nitrogen was merely excreted in the urine, and did not increase the heat production.

In the case of young animals that are growing and fattening, the feeding of a ration very high in protein may tend to make them grow more rangy and to lay on less fat than if fed rations lower in protein.

and thus be used in place of carbohydrate food.

Certain of the simpler amino acids can be made in the bodies of animals, either from some of the more complex amino acids or by combining ammonia or other simple nitrogenous compounds with organic acids formed from other food nutrients. However, the body is not able to synthesize several of the more complex amino acids in the body tissues, and these must therefore be provided from the proteins of the food. In certain cases the body may be able to make small amounts of an amino acid, but not enough to permit rapid growth.

QUALITY OF PROTEIN MAY BE AS IMPORTANT AS THE AMOUNT

Animals need not only plenty of protein in their food, but also protein of the right kind or quality. The pig on the left received plenty of protein, but his ration consisted of only grain and grain by-products, supplying protein of poor quality. The pig on the right, which is of the same age, received a ration of grain plus skimmilk, which supplied protein of good quality. (From Hart, Wisconsin Station.)

109. Essential amino acids.—It has been explained in Chapter I that proteins are exceedingly complex substances, made up of 24 or more different amino acids. In the digestion of food, the proteins are split into these amino acids, which are absorbed from the digestive system and enter the blood stream.

The mixture of amino acids is then carried in the blood to the various body tissues, where each organ or tissue takes the quantities of the different amino acids that it needs for its repair or functioning. As has been explained previously, the nitrogen is split off from the excess amino acids by the liver and this waste nitrogen is excreted in the urine by the kidneys. (51) The non-nitrogenous residue from the amino acids can be converted into glucose and glycogen

The amino acids which cannot be made in the body from other substances, or which cannot be made in sufficient amounts, are called the *essential amino acids.*

Protein for the growth of protein tissues of the body or for such purposes as the production of milk cannot be made by an animal unless it has an adequate supply of each of the essential amino acids. A shortage of a single one will limit the use of all the others, and therefore reduce the efficiency of the entire ration.

For example, let us suppose that an animal is building protein tissues that contain 5 per cent of a certain essential amino acid. However, the mixture of

amino acids furnished by the food contains only 1 per cent of this same amino acid. Five times as much food protein will then be required to form a given amount of body protein, as would be needed if the food protein supplied the same percentage of this essential amino acid as there was in the body tissue.

The nutritive value of a protein is not affected if it is deficient in one of the non-essential amino acids. Thus, casein, the chief protein of milk, is a protein of high nutritive value. Nevertheless, it has very little glycine, which is the simplest in structure of all the amino acids and is readily made in the body from other sources by most animals.

110. Determining which amino acids are essential.—Many experiments have been conducted with laboratory animals fed rations of highly purified nutrients to determine which of the amino acids are essential. In some of these investigations the only source of protein has been purified protein or artificially digested protein, which was known to be lacking in one or more amino acids. In other experiments mixtures of pure amino acids have replaced all the food protein.

The pioneer investigations to determine which amino acids are essential for animals were by Rose at the University of Illinois with young rats. Later studies have been conducted with human beings, with chicks, with young pigs, and with dogs.

In the experiments by Rose it was found that the following 10 amino acids are essential for the growth of rats: arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.[3]

A supply of arginine in the food is not needed for maintenance or for slow growth of rats, but they cannot synthesize this amino acid rapidly enough in their bodies to permit normal growth. Cystine, one of the two sulfur-containing amino acids, was formerly considered essential, but it has been found that cystine is not needed if the ration has enough methionine, the other sulfur-containing amino acid. Methionine is essential for growth. It can be replaced partially, but not entirely, by cystine.

Recently, the amounts of nearly all of the essential amino acids required by chicks and young pigs have been ascertained in careful experiments, which are summarized in Chapters XXXIV and XXXVI.

111. Differences in amino acid requirements.—The requirements of animals for the various amino acids differ, depending on the kind of animal and also on body function. Certain amino acids that are necessary for growth are not essential for merely maintaining a mature animal. For example, it has already been mentioned that arginine is necessary for normal growth of rats, but not for mere maintenance or for slow growth. Apparently, some of the other amino acids which are needed by rats for growth are not required for maintenance.

This can be explained by assuming that in the small daily breakdown and repair which takes place in the protein tissues of the body, entire protein molecules are not destroyed, but only certain groups split off. Then, the needs for maintenance would not involve building entire proteins, but only replacing these more simple groups.

The amino acid requirements of swine and dogs are similar to those of rats. Chicks need not only the 10 amino acids that are essential for rats, but also glycine (the simplest amino acid) and probably also glutamic acid.

So far is is known, the amino acid requirements for milk production resemble those for growth.

With the exception of glycine (the simplest amino acid), the amino acids can be in two forms—the L- form and the D- form. In proteins, only the L-forms occur, and in the case of most of the amino acids, these are the only form which can be utilized by animals. The D- form of tryptophan can be used to a limited extent.

Certain of the amino acids have been synthesized chemically, and some of these are now being made commercially. In most cases, these are mixtures

of both forms of the amino acid. The use of the synthetic amino acids as supplements to rations is discussed in the chapters dealing with the respective classes of farm animals.

112. Requirements of ruminants and horses much more simple.—Fortunately, ruminants and horses have much more simple requirements for protein than do rats, dogs, pigs, chickens, or man. This is because the bacteria and other micro-organisms which are so important in the digestion of fiber by these animals are able to use for their food very simple nitrogenous compounds, which the animals could not themselves use at all.

The bacteria build these simple forms of nitrogen into complete proteins in making the cells of which they are composed. Then, further on in the digestive tract of the ruminant, these bacterial cells are digested, and the protein that has been made by the bacteria is thus made available to the animal.

Experiments have proved that all 10 essential amino acids can be thus made by the rumen bacteria from simple forms of nitrogen in the food.[4] Therefore the bacterial protein may provide all of the essential amino acids, even though they are lacking in the feed which the ruminant eats. A similar action occurs in the caecum and colon of the horse.

For this reason, in the feeding of dairy cows, beef cattle, sheep, and horses, much less attention need be given to the kind or quality of protein in the ration than is needed in the feeding of swine or poultry. As is shown later, even such simple substances as urea can be used satisfactorily to replace a considerable part of the protein in feeding dairy cattle and beef cattle. For the first few weeks after birth, before the rumen has developed sufficiently, young ruminants need protein of good quality that supplies the essential amino acids.

Another reason why the quality of protein is usually not of major importance in feeding dairy cattle (except young calves raised on a minimum amount of milk) and in feeding beef cattle, sheep, and horses, is that a large part of their rations generally consists of roughage. The quality of protein in good pasturage, hay, or silage is superior to that in the cereal grains, which often form most of the rations for swine and poultry.

113. Other nutritive essentials in protein.—In some of the nutrition experiments with rats and mice, used as test animals, growth has not been so rapid on mixtures of pure amino acids, substituted for protein, as on a diet containing natural protein. It therefore seemed that some other necessary factor besides the known essential amino acids was supplied by food protein.[5] This factor has been called "strepogenin," and may have been certain peptides, which are combinations of amino acids that are simpler than protein.

In recent Wisconsin experiments, however, entirely normal growth of rats was secured on a diet in which an improved mixture of pure amino acids furnished all the nitrogen.[6] On the other hand, in trials with chicks and laying hens, it has not been possible to secure satisfactory results on a mixture of pure amino acids as a substitute for all the protein.[7] The question as to whether food protein supplies some other essential than amino acids is therefore still unsolved.

114. Quality of protein; supplementary effect.—Many of our common feeds contain too small amounts of one or more of the essential amino acids to produce good results when used as the only source of protein for such animals as swine or poultry. On the other hand, a few feeds, such as milk, eggs, and meat, supply the various amino acids in very nearly the proper proportions for complete utilization.

Feeds or rations that furnish insufficient amounts of any of the essential amino acids are said to have *protein of poor quality*. Those which have the proper proportions of all of the essential amino acids are said to supply *protein of good quality*.

Fortunately, the feeds that have proteins of poor quality are not all deficient in the same amino acids. For this

reason the proteins in two feeds, each of which furnishes poor-quality protein when fed alone, may supplement each other in a very important manner. For example, the quality of protein in corn grain is poor because corn protein is low in lysine and tryptophan, which are two of the essential amino acids for such animals as swine and poultry. As is shown in later chapters, tankage, a meat by-product, is an effective supplement to corn in feeding swine and poultry. This is true even though the quality of protein in tankage is low when it is fed as the only source of protein. (Much of the protein in tankage consists, not of meat tissue, but of protein in gristle, connective tissue, and bones, which is of poor quality.)

Another good illustration of the supplementary effect of proteins is the manner in which milk corrects the deficiencies in the proteins of the grains. Milk is able to correct the lacks in grain protein, because it is rich in lysine, which is low in all the grains. Also, it is rich in tryptophan, which is deficient in the protein of corn and some other grains.

The manner in which milk makes good the deficiencies in corn protein is shown by Wisconsin experiments in which young pigs were fed rations containing protein from various sources. When pigs were fed only wheat, corn, or oat grain, they stored in their bodies but 23 to 28 per cent of the total protein in their feed.[8] On the other hand, when skimmilk was the sole source of protein, they were able to store 66 per cent of the protein supplied by the milk.

A mixture of one-third each of corn, wheat, and oats was only a trifle better than any one of the cereals alone, for they are all deficient in lysine. However, when pigs were fed 1.3 lbs. of skimmilk to each pound of corn, they made 62 per cent of the total protein in their feed into body tissues. The milk was thus rich enough in lysine and tryptophan to make the combination of corn and milk nearly as efficient as milk, which is often called the ideal food.

This well shows that it is unnecessary for each feed in a ration to furnish protein of high quality. All that is needed is a sufficient amount in the entire ration of each of the essential amino acids.

115. Effect of excessive heating; of long storage.—Too much heat in a manufacturing process injures the quality of protein in feeds by destroying or making unavailable certain amino acids, especially lysine, tryptophan, arginine, and histidine.[9] It is pointed out in Chapter XXII that although the value of soybean oil meal for non-ruminants is decidedly improved by thorough cooking, too high heating injures it. (793) Also, the flame-drying of such a by-product as fish meal decreases the value of the protein, in comparison with drying at a lower temperature. (917) In the commercial drying of grain, too high a temperature reduces the protein value.[10]

The decrease in value of grain damaged in elevator or other fires will differ widely, depending on the actual amount of damage by heat or charring, or by water with subsequent molding. In some cases such grain may be worth nearly as much as sound grain, and in others it may have little value.

The storage of well-dried corn or wheat for as long as 2 to 3 years did not appreciably lower the value of the protein in Illinois tests, but storage for only a year definitely reduced the digestibility and availability of the protein in soybean seed.[11] In trials by the United States Department of Agriculture with various lots of corn stored as long as 6 years, in some cases the efficiency of the protein was much reduced, but not in others.[12]

116. Time factor in protein supplementation.—Recent studies indicate that for certain animals the feeding of a protein supplement some hours after the other feed is eaten may reduce the effectiveness of the supplement.[13] This could be explained as follows: If the animal is fed corn every day, but is fed a protein supplement only every other day, there will be in its body a deficiency of lysine and tryptophan during the day in which no supplement is fed. The other amino acids resulting from the di-

gestion of the corn can therefore not be used effectively and they cannot be stored in the body until the next day. There is consequently an increased wastage of amino acids through deamination. (51)

Experiments with young rats have shown that delaying for several hours the feeding of an amino acid which was deficient in the diet, decreased the formation of protein tissue in the body. This time factor may be less important in the feeding of livestock, because of the longer time the food remains in the digestive tract. In a Nebraska experiment a 24-hour delay in giving the protein supplement to young pigs fed corn did not decrease the growth or the formation of protein tissue.[14] A still longer delay in feeding the supplement was appreciably detrimental.

However, it is shown in Chapter XXVIII that in Kansas trials the gain was much less when young beef cattle being wintered on mature range pasture were fed a double allowance of protein supplement every other day to save labor, instead of the normal amount each day.

117. Amino acid content as a measure of value.—Until recently, it was not possible to find accurately the percentages of the various amino acids in feeds, because the carbohydrates interfered with the determinations. Information could therefore be secured only on the amino acid content of pure proteins, such as corn zein, which had been extracted from the grain and purified.

Fortunately, methods have now been developed for determining the content of the different amino acids in entire feeds. After the protein in the feed is broken down as completely as possible by digestion with acid or otherwise, the percentages of the various amino acids are found. For most of the amino acids, the rapid microbiological method is used, in which the amount of an amino acid is determined by the rate of growth of certain bacteria which require the particular amino acid.

As yet, the results secured by various investigators differ appreciably, but information has been obtained which shows approximately the content of the different essential amino acids in some of the most important concentrates. But little such data is available for roughages, except for alfalfa meal.

Appendix Table X states the approximate percentage of certain amino acids in some of the most important feeds, so far as data are available. Such information is helpful in formulating efficient rations for pigs and poultry, as it shows how feeds can be combined to meet the known requirements for the different essential amino acids.

118. Measuring the values of protein in feeds.—Because of the difficulty in determining accurately the amounts of each of the essential amino acids in a feed, the information concerning the nutritive value of various feeds as sources of protein has been gained chiefly through practical feeding experiments. A great number of experiments of this kind are summarized in Parts II and III of this book.

In such investigations the animals are fed rations in which various protein supplements or mixtures of feeds are directly compared, and the production on each ration carefully determined. Care must be taken to make sure that the experimental rations fully meet all the requirements for energy, minerals, and vitamins. Otherwise, the utilization of the protein will be decreased by a lack of other nutrients. It is just as important that no more protein be fed than is actually needed, or some will be wasted.

In experiments in which it is desired to compare the value of the protein in various rations, each ration must have the same percentage of protein. This is because the percentage efficiency with which protein is used depends on the level of protein in the ration.

This principle is of great importance in practical feeding experiments. If two protein supplements are being compared which contain considerably different percentages of protein, correspondingly less of the supplement richer in protein should be used.

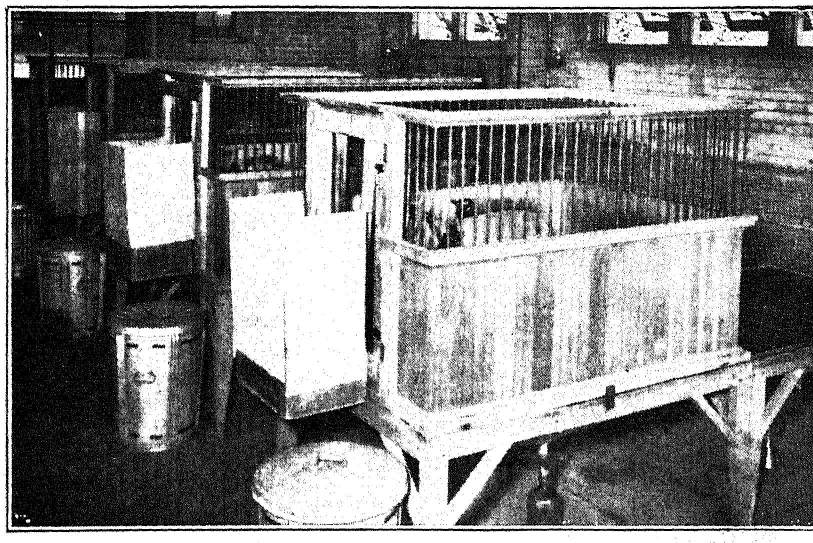
If enough of the low-protein supple-

ment is fed to balance the ration in protein content and the same amount of the high-protein supplement is included in the other ration, it should be evident that there will be an excess of protein in the latter ration. Part of the high-protein supplement will then be wasted, so far as its use as a protein supplement is concerned. On the other hand, if just enough of the high-protein supplement is used to balance one ration and no more of the low-protein supplement is included in the other ration, the latter will not supply enough protein for optimum results.

Therefore, whenever this fundamental principle is neglected, either one or the other of the rations will be made less efficient than it should be, solely because the experiment was not properly planned. Unfortunately, this simple principle has not been considered in certain of the comparisons that have been made of protein supplements.

119. Biological values; other measures of protein quality.—The most common laboratory method of measuring the nutritive value of the protein in a ration is to determine the *biological value*. This is the percentage of the digested protein that is used for both maintenance and growth. In such an experiment, the feces and the urine voided by the experimental animal are carefully collected and analyzed, so as to find the amount of protein stored in the body.

In this method a protein that was used with perfect efficiency for maintenance and growth would have a biological value of 100 per cent. Few feeds even approach this theoretical efficiency, and a value of 90 per cent or more proves that the protein in a feed has an unusually high efficiency. Biological values of 75 to 90 per cent indicate that the protein is considerably better than average.



DETERMINING NUTRITIVE VALUE OF PROTEIN IN RATIONS

Experiments are being conducted with lambs in these metabolism cages to determine the nutritive value of the protein in different rations. The feed is accurately analyzed and weighed, and all feces and urine are collected and analyzed. (From Cornell University.)

In such metabolism experiments the results can also be stated in terms of the percentage of total protein or of digestible protein that is stored by the animal. In similar tests with lactating animals, one can find the percentage of food protein that is secreted in the milk.

The "gross protein value" method has been used at the Washington Station to find the relative value, in comparison

with casein, of various protein supplements for balancing a base diet made up of farm grains, mill feeds, and alfalfa meal.[15]

In the carcass analysis method, used sometimes in experiments with laboratory animals, the amount of protein stored in the body on each ration is determined by analysis of the carcasses of animals fed the ration, in comparison with the analyses of similar animals slaughtered at the beginning of the trial.

A chemical method sometimes used to measure the quality of protein in various protein supplements is to digest the feed in a solution of pepsin or other enzymes and hydrochloric acid.[16] The portion not digested is considered valueless. This method seems to be useful for fish meals and packing-house by-products, but is less reliable for other feeds.

120. Protein of cereal grains and by-products.—Since the cereal grains and their by-products form such a large part of the concentrates fed farm animals, it is essential that the nature of their protein be thoroughly understood. When fed as the only source of protein, the grains all fall decidedly below such a food as milk in quality of protein.

The results have differed considerably in the experiments to compare the quality of protein in the various grains, when furnishing all or nearly all the protein in the ration. Generally, the protein of corn has been less efficient for growth than the protein of barley, oats, or wheat. Also, corn generally has considerably less protein than these other grains. All of the grains are low in lysine, and corn and milo are deficient in tryptophan as well.

When the cereal grains have been fed to pigs, chicks, or rats as the only source of protein, the biological value of the protein has usually ranged between 60 and 70 per cent when the rations have had 8 to 10 per cent protein. In comparison with this, the protein in milk has generally had a biological value of 85 to 90 per cent or more. Highly-milled flour made from the cereals, such as patent wheat flour, has somewhat poorer quality protein than the entire grain.

No good stockman feeds his animals grain alone. In livestock feeding the important question is therefore how the deficiencies of the protein of the grains can be corrected by proper combination with other feeds. It has been previously shown that milk effectively makes good the lacks in the protein of grain. (114) Other protein-rich feeds that efficiently supplement the protein of the grains are fish meal, meat scrap, tankage, soybean oil meal, and peanut oil meal. These and other protein supplements are discussed later in this chapter, and further information concerning the manner in which they supplement the grains is given in the chapters of Part III.

The germs of the cereal grains furnish protein of better quality than the rest of the kernels. Also, the bran layers of wheat have better protein than the endosperm portion. Therefore wheat bran and wheat middlings supply better protein than the entire wheat grain.[17] Likewise, corn oil meal (made from the corn germs) has better protein than the entire corn grain or than corn gluten feed. Similarly, the protein in rice bran and rice polish is of much better quality than the protein in the entire rice kernel.[18]

Though these particular cereal by-products have better protein than the entire cereal grains, none is satisfactory as the only protein supplement to grain for feeding swine or poultry. For the best results it is necessary to combine them with such feeds as milk, fish meal, meat scrap, or soybean oil meal, which more effectively correct the deficiencies of the cereal protein.

Corn gluten feed and corn gluten meal resemble corn grain in deficiencies in quality of protein. For swine or poultry these corn by-products should be combined with protein supplements that correct these deficiencies.

121. Feeds of animal origin.—The values of the various protein supplements of animal origin are discussed in detail in Chapter XXIII. As has been emphasized previously in this chapter, milk pro-

tein makes good the deficiencies of the cereal proteins in a very complete manner. Casein, which forms over three-fourths of the protein in milk, is but slightly inferior to the entire mixture of proteins that milk contains.

Lactalbumin, or milk albumin, which forms most of the rest of the milk protein, is of even higher value than casein. The protein of whey is chiefly lactalbumin. It is therefore not surprising that whey is very effective in correcting the deficiencies in the protein of the cereal grains, even though whey has only a small percentage of protein on the dry basis.

The proteins of eggs, meat, and fish are also of unusually high nutritive value, a fact that is of great importance in human nutrition. The protein of eggs is equal or superior to that of milk, and meat and fish rank but slightly below in quality of protein. Animal tissues that consist mostly of gristle and connective tissue are of much lower value than muscle or most glandular tissue, such as liver or kidney.

For swine and poultry feeding, the meat and fish by-products are popular protein supplements. Meat scrap and tankage correct the deficiences of the protein of the grains, but are less effective single protein supplements to the grains than are soybean oil meal or fish meal. The protein value of much of the meat scrap and tankage now made seems to be lower than that made years ago, presumably because it is more largely composed of gristle and connective tissue. (**902**) Fish meal consisting mostly of fish heads has a lower value than that made chiefly of muscular tissue.

Blood meal of the usual kind is not high in digestibility, and the protein is apparently not of as high nutritive value as that of meat scrap or tankage.[19]

122. Protein of legume seeds.—The proteins of the various legume seeds and their by-products differ to a surprising degree in nutritive value. For the feeding of swine and poultry, we can give top rank among protein-rich feeds of plant origin to the protein of soybean oil meal that has been properly cooked in the manufacturing process. Indeed, such soybean oil meal equals or comes close to milk in making good the deficiencies in the proteins of the grains.

The protein of raw soybeans is of much lower value for swine, poultry, or such laboratory test animals as rats, because thorough cooking is required to make the methionine and cystine in soybeans fully available to these animals. However, if the cooking is too severe, the nutritive value may be decreased. Cooking soybeans does not appreciably improve the value of soybean protein for such ruminants as cattle over 1 year of age or sheep.

For swine not on pasture, especially young pigs, and also for poultry, rations consisting of soybean oil meal, grain, and grain by-products are generally improved somewhat by the addition of a small amount of meat scrap, tankage, fish meal or skimmilk.

It is shown in Chapter XXII that the value of peanut oil meal as a protein supplement equals or closely approaches that of soybean oil meal. Cooking improves peanut protein less than soybean protein.

Peas are a very satisfactory feed for livestock, except for the fact that they are usually expensive. However, the protein of peas does not supplement that of the cereals as completely as does that of soybean oil meal, because of a deficiency of methionine. (**855**) Therefore in poultry feeding peas cannot be used to replace as large a proportion of the animal-protein supplements as is possible with soybean oil meal.

Most beans and also cowpeas and lentils have protein of much poorer quality than does soybean oil meal. Also, beans are utilized very poorly by swine and poultry unless they are thoroughly cooked.

The values of other legume seeds are discussed in Chapter XXII.

123. Protein of other concentrates.—Detailed information is given in the various chapters of Part II concerning the many other protein supplements available for stock feeding. On account of the importance of linseed meal and

cottonseed meal, the nutritive value of their protein is of especial interest. These are excellent supplements for dairy cattle, beef cattle, sheep, and horses.

For swine or poultry, the protein of linseed meal does not effectively supplement the protein of the grains, probably because it contains less lysine than does soybean oil meal. Therefore for swine or poultry linseed meal should be used in combination with such a supplement as soybean oil meal, fish meal, meat scrap, or tankage, which supplies more lysine. (829) It is shown in Chapter XXII that for another reason than quality of protein linseed meal is not satisfactory as any important part of a ration for poultry. (836)

Ordinary cottonseed meal can be used in only very limited amounts for swine or poultry, because of the gossypol content. (811) Recently, methods have been developed for producing de-gossypolized cottonseed meal, which can make up a larger part of their rations. (812) Even this cottonseed meal should, however, be fed in combination with such protein supplements as fish meal, soybean oil meal, meat scraps, or tankage.

Coconut oil meal is not satisfactory as the only protein supplement to the cereal grains for feeding swine or poultry.

Dried brewers' yeast and other yeasts, which are rich in B-complex vitamins, are also rich in protein and can be used as protein supplements in stock feeding. However, yeast should not be used as the only protein supplement to grain for swine or poultry.

Distillers dried solubles are also very rich in B-complex vitamins and rich in protein, but the protein is not of good quality for poultry or swine. It did not supplement corn protein in Indiana tests, because it was low in the same amino acids.[20]

Nuts, except peanuts, are rarely used for stock feeding. It is of interest to note, however, that although nuts are rich in protein, the protein of most nuts was decidedly inferior to that of meat in Illinois tests.[21]

124. Protein of forage crops.—There is but little exact information concerning the value of the protein in pastures, hay, and silage, for swine and poultry or for other animals that need protein of high quality. However, practical feeding experiments show that the protein of most first-class roughages is at least of fairly good quality, and that it corrects to a considerable extent the deficiencies in the proteins of the grains.

Pigs on excellent pasture, such as alfalfa, clover, or rape, make reasonably good growth when fed only corn or other grain, plus a mineral supplement. However, such a ration is too low in amount of protein for the most rapid growth, especially of young pigs. Also, the quality of the protein can be made still better by adding to the ration such a protein supplement as skimmilk, meat scrap, or fish meal.

Similarly, for poultry excellent pasture, such as Ladino clover, other clovers, or alfalfa, greatly reduces the need for high-quality protein supplements, such as meat scrap or milk by-products.

125. Protein in non-legume forage.—From the excellent growth made by young cattle, sheep, and horses on good grass pasture, we can conclude that there is no deficiency for such animals in the quality of protein supplied by most kinds of young grass.

Some experiments to compare the value of the protein in grasses and other forages have been conducted with rabbits and guinea pigs, used as laboratory test animals. Both rabbits and guinea pigs are able to digest such roughage fairly efficiently through bacterial action in the digestive tract, though less completely than do cattle or sheep. In Arkansas tests with guinea pigs there was not much difference in the biological value of the protein of most kinds of young grass and of legume forage, but the protein in the legume forage was digested to a slightly greater extent.[22] In Florida experiments the quality of Bermuda grass protein for rabbits was nearly as good as that of a clover-grass pasture.[23]

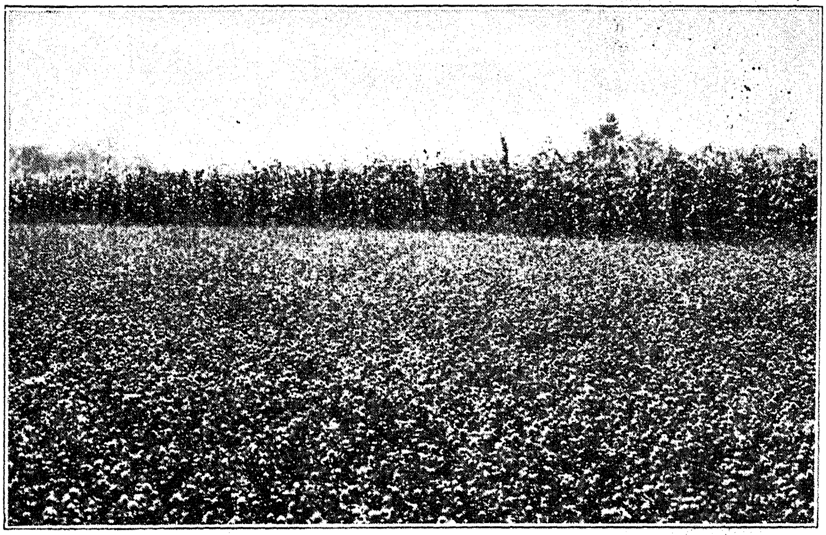
In Canadian tests with rabbits the

protein of mixed grasses from a fertilized plot was of higher value than that of grass from an unfertilized area.[24] Also, the protein in young timothy was of decidedly higher value than that of young reed canary grass.

Other experiments have indicated that although the amount of protein in corn silage and wheat straw is low, the quality of protein in this small amount of protein is satisfactory for lambs.[25]

for dairy cows, beef cattle, sheep, and horses. Red clover hay likewise furnishes protein of good quality for these animals, but it is somewhat lower than alfalfa in amount of protein.

Investigations have shown that legume hay even provides protein of good quality for ruminants when it is fed as the only source of protein. This was proved in metabolism experiments with growing lambs at the New York (Cor-



LEGUME FORAGE INSURES GOOD PROTEIN FOR RUMINANTS

A fine crop of red clover in the foreground, with corn in the background. Such a combination as clover or alfalfa hay and corn grain provides good quality protein for ruminants.

126. Legume forage insures good-quality protein for herbivora.—One of the exceedingly important facts in livestock feeding is that legume forages admirably supplement the grains in feeding dairy cattle, beef cattle, sheep, and horses. This is emphasized in Chapter XVI.

First of all, legume forages are rich in protein. Also, the combination of grain and legume forage furnishes protein of very satisfactory quality for these animals. It is shown in later chapters that merely an abundance of well-cured alfalfa, soybean, or cowpea hay, fed with farm grain and without any high-protein supplement, makes a satisfactory ration

nell) Station.[26] When growing lambs were fed either alfalfa hay or red clover hay as the sole source of protein in a ration supplying plenty of carbohydrates and fat, the biological value of the protein was high. Indeed, the protein of the legume hay or of legume hay and corn grain was just as efficient as the protein of soybean oil meal or of dried skimmilk. Similar results were secured in Missouri experiments with dairy heifers.[27]

127. Quality of protein in feeding cattle or sheep.—A question of much importance is whether or not it is necessary to give any consideration to quality of protein in the practical feeding of dairy cattle, beef cattle, or sheep. Detailed in-

formation concerning this problem in feeding each of these classes of stock is given in the respective chapters of Part III.

In general, it seems safe to conclude that for cattle or sheep there is not apt to be any deficiency in the quality of protein when any considerable part of the roughage consists of legume forage. If enough legume hay or even mixed hay high in legumes is fed, good results can be secured when the only protein supplement is such a feed as corn gluten meal or corn gluten feed, both of which have proteins of rather poor quality. If only non-legume roughage is fed, especially that of poor quality, then the kind of protein supplied by various protein supplements may sometimes be important.[28]

A possible explanation of such differences with good-quality roughage and poor roughage may be the following: When all of the roughage is of poor quality, the bacterial fermentation in the rumen may be so changed that there is less formation of good-quality protein by the bacteria from the nitrogenous compounds in the feed.

In raising dairy calves chiefly on milk substitutes, attention must be given to the quality of protein in the ration for the first few weeks, until the rumen has developed enough for the calf to consume and utilize considerable roughage.

128. Amino acid supplements.—If a ration for pigs or poultry is deficient in one of the essential amino acids, the lack can be corrected by including a feed that has a good supply of this amino acid, or else by adding a small amount of the pure amino acid. The amino acid requirements of pigs and poultry and the ways in which a lack of essential amino acids can be corrected by a suitable protein supplement are discussed in Chapters XXXIV and XXXVI. Commercial products are also on the market, prepared from natural feeds, which are rich in certain of the essential amino acids.

Through the recent commercial production of some of the essential amino acids synthetically, it has become possible to use a pure amino acid to supplement a ration which has too small an amount of that amino acid. Thus far, methionine and lysine are the only essential amino acids produced at a sufficiently low cost to make such use practical. Methionine is available at approximately $1.50 per pound, and synthetic lysine is about $4.50 per pound. Other amino acids are much more expensive.

The use of synthetic methionine in rations for pigs and poultry is treated in Chapters XXXIV and XXXVI. Such supplementation with methionine has thus far been used chiefly in rations for chicks and turkey poults.

129. Urea as a protein substitute.—With our present livestock population, insufficient amounts of protein supplements are available to balance properly the rations for all the farm animals. It is therefore fortunate that many thousands of tons of urea, which can be used as a partial protein substitute for certain classes of stock, are manufactured each year from the nitrogen of the air for use in industry and agriculture.

Each pound of urea, which is a very simple nitrogenous compound, contains as much nitrogen as 2.9 pounds of protein. To reduce the trouble from caking in storage, a small amount of other material is mixed with the feed urea to give a product containing as much nitrogen as though it had 262 per cent of protein.

Numerous investigations have shown that when urea is added to a suitable ration for ruminants, the bacteria in the rumen can convert it more or less completely into protein in their cells during the fermentation which occurs normally in the rumen digestion.[29] The urea is first changed rapidly into ammonia in the rumen, and this is combined with non-nitrogenous compounds in the building of the bacterial protein. Further on in the digestive tract, the bacteria are digested, and the protein is thus made available to the animal. (44)

The conversion of urea into protein is not efficient when the ration does not have a readily available supply of energy for the bacteria, or when urea is

added to a mixture that is already fairly high in protein.

When urea is added to a concentrate mixture which has the usual amount of cereal grains, the conversion into protein is satisfactory, as the starch in the grain furnishes plenty of energy for the bacteria. The conversion of urea into protein is poor when urea is added to hay alone, without any concentrates. Also, the conversion is not satisfactory when urea is added to molasses and such roughage as grass hay. However, urea can be converted into protein effectively when the concentrate mixture contains a good supply of grain, along with some molasses. For sheep, which have a high sulfur requirement in wool production, the utilization of urea may be increased if sulfur is added to a ration which is low in this mineral.

Too large an amount of urea in a concentrate mixture may make it unpalatable, and animals may be poisoned if they consume more than a certain amount of urea. Therefore not more than 2 to 3 per cent of urea should be included in the total concentrates fed. Also, urea should not form more than 5 to 10 per cent of protein supplemental mixtures or pellets, or the palatability may be much decreased.

Urea must be mixed very thoroughly and carefully in a mixture, to prevent any animal from getting a dangerous amount. Deaths of stock have been caused in a few instances by mixed feeds, containing urea, which were not prepared with sufficient care.

It must be borne in mind that urea furnishes no energy to an animal, while the common protein supplements furnish both protein and energy. Therefore when protein-rich feeds cost but little more than the farm grains, the use of urea is uneconomical. For example, even if the nitrogen in urea is used as efficiently as the nitrogen in a protein supplement, it will require about 14 lbs. of urea plus 100 lbs. of corn or other grain to replace 100 lbs. of soybean oil meal.

If a ration already has enough protein, there will be no advantage in adding urea to it. Thus, it is shown in Chapter XXV that for dairy cows a concentrate mixture having 16 to 18 per cent protein supplies plenty of protein for feeding with corn silage and good mixed hay containing at least one-third legumes. (1017) There will be no benefit from adding urea to such a concentrate mixture, so as to increase the protein equivalent to 20 per cent or more.

The use of urea as a protein substitute for dairy cattle, for beef cattle, and for sheep is discussed in the chapters dealing with these classes of stock. Urea has given the most satisfactory results when it has replaced not more than one-fourth to one-third the protein in a ration, and when there was considerable grain in the mixture. It has usually not been an effective protein substitute when used without grain, but mixed only with molasses or alfalfa meal. Urea has been used chiefly in formula feeds (commercial mixed feeds) for dairy cattle and beef cattle. It has also been a fair substitute for part of the protein in rations for pregnant and lactating ewes, but in some of the experiments with fattening lambs it has not been an effective protein substitute.

Urea has little or no value as a protein substitute for swine or poultry, or for dairy calves before the rumen is well developed.[30] However, a properly mixed urea-containing feed will not poison these animals if they chance to eat some of it.

Differing from certain advertising claims made for urea, feeding experiments have shown that even with poor roughage, rations containing urea generally give no better results than when all the protein is supplied by natural feeds.

130. Urea-treated silage.—In some experiments urea has been added to green forage as it was ensiled, to increase the protein value of low-protein silage, such as corn or sorghum.[31] Beef cattle being wintered do better on such silage than on corn or sorghum silage with no protein supplement, but may not gain quite so well as on normal silage and a protein supplement.

In some tests the addition of urea to

silage has reduced the palatability, and in a Florida trial a considerable part of the added nitrogen was lost from the silage as ammonia or by leaching.

131. Other protein substitutes.—By adding ammonia to certain low-protein feeds, ammoniated products have been made, which might serve, like urea, as partial protein substitutes. These have included ammoniated cane or corn molasses, ammoniated citrus pulp, ammoniated beet pulp, ammoniated condensed distillers molasses solubles, and ammoniated furfural residue.

In recent New York experiments the nitrogen in ammoniated molasses, ammoniated citrus pulp, and ammoniated distillers molasses solubles was much less available to rumen bacteria or to steers than the nitrogen of urea.[32] Similar results were secured with ammoniated molasses in recent Ohio tests.[33]

In some feeding experiments *ammoniated molasses* has given results similar to those with urea.[34] However, in other trials cattle and sheep have had extreme nervous symptoms after receiving ammoniated cane molasses only a few days, acting crazy.[35] Death has sometimes followed unless the feed was discontinued.

Ammoniated condensed distillers molasses solubles has been a fairly satisfactory substitute for part of the protein supplement.[36]

Ammoniated citrus pulp was less palatable than plain citrus pulp to beef cattle, and produced less gain than cottonseed meal.[37]

In an English test *ammoniated beet pulp* was worth less than ordinary beet pulp,[38] and in a Colorado trial it had no advantage over alfalfa hay as a source of protein for fattening cattle.[39]

Ammoniated furfural residue in one experiment decreased the gain of beef cattle when replacing half the cottonseed meal in the ration.[40]

By heating urea, *biuret,* a less soluble condensation product, is formed. Since this is less toxic than urea if a large amount is consumed, its value as a protein substitute is being tested. In recent trials lambs gained slightly less with biuret as a protein substitute than with urea.[41]

In an experiment with dairy heifers another nitrogen compound, *dicyanodiamide,* produced slightly smaller gains than did soybean oil meal.[42]

II. Fats in Livestock Feeding

132. Functions of fats.—It has been shown in Chapter I that several groups of substances besides the true fats are included in the ether extract, or so-called "fat" of feeds and animal tissues. (13–14) Though present in only small amounts, certain of these substances are very important in animal nutrition.

For instance, vitamin A, carotene, and vitamin D, which are discussed in Chapter VII, are soluble in fat solvents and are therefore included in the ether extract. Cholesterol and the phospholipids, which are essential constituents of the body, are other important components of ether extract, though usually present in very small amounts. Vitamins E and K are likewise soluble in ether and are thus included in the ether extract.

In seeds most of the ether extract is true fat. On the other hand, in forage crops more than one-half of it may consist of other compounds, especially chlorophyll, which apparently has no food value to animals. The digestion, absorption, and utilization of fat in the body have been explained in Chapter II. (47, 51)

The fat in foods serves as a source of energy, the same as the carbohydrates. Also, body fat or the fat in milk can be formed from the fat in the feed. Fat is a much more concentrated source of energy than the carbohydrates, for digestible fat furnishes about 2.25 times as much energy per pound as is contained in digestible carbohydrates. For this reason, a concentrate mixture very low in fat is generally lower in total digestible nutrients than one having more fat.

Fat is not only a concentrated source of energy and of body fat or milk fat, but it also has other functions. It aids in the absorption from the food of vitamin A and especially of carotene, and

may help in the absorption of calcium. Experiments have also shown that the net-energy value of a ration is decreased if it is unusually low in fat. (78)

Fat forms a considerable part of the food of suckling animals. For example, fat forms as much as one-third of the dry matter of cow's milk. It is pointed out in Chapter IX that for very young calves, especially for those that are not vigorous, milk that is not unduly rich in fat is better than very rich milk. (269)

For certain animals, fats that have a high melting point are less digestible and of less value than fats which have a lower melting point. However, for farm animals, except possibly poultry, there does not seem to be such a difference.[43]

The effect of the kind of fat in the ration upon the character of body fat or milk fat made by animals is discussed in Chapter IX and in the chapters of Part III.

133. Need of fat by farm animals.—The question as to whether farm animals require a certain minimum amount of fat in their rations for optimum results is now of greater importance than formerly, because of the wide use of the solvent process of extracting fat very completely from such oil-rich seeds as soybeans and from some by-products high in fat.

It has been shown in previous chapters that carbohydrates can serve not only as the source of energy in the body, but also as the source of body fat and milk fat. However, experiments summarized in the chapters dealing with the various classes of stock have proved that young calves, lambs, pigs, and chicks need a certain minimum amount of fat for growth and health.

Experiments with dairy cows reviewed in Chapter XXV also show that the yield of milk is reduced when the concentrate mixture is too low in fat. (**1020**) In these experiments and in trials with pigs, the difference in value per 100 lbs. of rations low in fat and moderate in fat was greater than the difference in energy value as ordinarily computed. In other words, the additional amount of fat was worth more than 2.25 times as much as an equal weight of digestible carbohydrates.

Experiments with laboratory animals fed diets containing almost no fat have shown that rats, mice, and dogs require for growth and even for health small amounts of certain unsaturated fatty acids, such as linoleic acid, which are present in most natural fats. These are called the essential fatty acids.

Whether farm animals need these fatty acids (linoleic, arachidonic, and linolenic) is still unknown. In New York experiments young calves could not live on a fat-free diet, but the fat deficiency was corrected by including 2 per cent of hydrogenated coconut oil, which contains no unsaturated fatty acids.[44] This indicates that the deficiency was not a lack of essential unsaturated fatty acids.

134. Adding fat to rations.—Except under special conditions, carbohydrates furnish energy for farm animals more cheaply than do fats. Therefore the ability of livestock to utilize increased amounts of fat in their rations has not until recently been of practical importance.

During the past few years, there has been a large surplus in this country of by-product animal fats, produced in the meat and rendering industries. As a result, the prices of these tallows and greases have fallen to levels that make their use in livestock feeds practical. This surplus has come about chiefly because of the advent and wide use of detergents in the soap industry, and the desire of consumers for meat cuts from which more of the surplus fat has been trimmed.

In the manufacture of formula feeds, or mixed commercial feeds, the addition of 1 to 2 per cent or more of such fats reduces dustiness and may improve the color, texture, and palatability of the feed. Because fat is a lubricant, adding it makes the feed mixture less abrasive to machinery, such as mixers, conveyors, and scales. This lubricating quality of added fat also appreciably increases the capacity of pelleting machinery. In this country, a small amount of such animal fat is now added to some

of the commercial alfalfa meal to reduce dustiness and improve the color.

To prevent the development of rancidity, it is essential to use fat to which an approved antioxidant, or stabilizer, has been added in proper amount. When a stabilized fat is added to a feed mixture, there is a tendency for the loss of vitamin A and of xanthophyll during storage to be reduced.[45] On the other hand, the use of unstabilized fat in a mixture increases the loss of vitamin A and vitamin E.

Animal and vegetable fats seem to be equally effective additions to feeds, but ordinarily by-product animal fats are much cheaper than such plant fats as soybean or cottonseed oil. Hydrogenated fats, or stearic acid, which have a melting point above body temperature, are not well utilized, at least by poultry. Also, a fat that is very solid at ordinary temperatures does not reduce dustiness and improve appearance like liquid or softer fats.

The experiments in which by-product fats have been added to rations for the various classes of stock are summarized in the chapters dealing with the different kinds of farm animals.

135. Does the fat of milk have special value?—It is well known that one of the great values of milk as a human food and as a food for all young mammals is the high vitamin A value of the fat. Many experiments have been conducted in an endeavor to find whether the fat of milk has other special values, most of the tests having been with young rats started on the experimental diets after weaning. In such studies care is taken to supply in all diets an abundance of vitamin A and other vitamins that may be furnished by butterfat. In some of the investigations the young rats have made better growth on diets containing milk fat, when lactose was the carbohydrate food. However, in other tests there has been no difference in the results from milk fat and other fats.

In experiments in which dairy calves have been raised from birth on semi-purified diets or on milk replacers containing ample vitamins, the calves grew poorly and usually died when fed ordinary plant oils, such as soybean oil or cottonseed oil as a substitute for milk fat. However, when lard or homogenized hydrogenated plant fat was used, the growth was nearly normal, though sometimes slightly less than on milk fat. (1114)

These results indicate that for very young animals various kinds of fat may differ decidedly in value, even when an abundance of vitamin A is provided from other sources.

III. Carbohydrates in Livestock Feeding

136. Value and functions of various carbohydrates.—The carbohydrates in feeds differ greatly in digestibility and nutritive value, as has been shown in previous chapters. Starch and the sugars are readily digested and have a high feeding value. Cellulose and the other very complex carbohydrates are digested only through the bacterial action that occurs in the rumen of ruminants, in the caecum and large intestine of horses, and to a much less extent in the large intestine of other animals. By this means ruminants, such as cattle and sheep, and also horses are able to digest and utilize the fiber of feeds fairly well, though it has a much lower value for them than starch. Swine or poultry can make very little use of fiber. Lignin is digested to only a very small extent, even by ruminants.

It has been shown in Chapter II that in the process of digestion starch is changed to glucose. Compound sugars are also converted almost entirely into glucose or other simple sugars and absorbed into the blood in this form. In the bacterial digestion of fiber the chief useful products are organic acids, largely acetic acid. Experiments have shown that these organic acids are absorbed and used in the body the same as glucose.

Since carbohydrates form about three-fourths of the dry matter in most plants, they are the chief source of energy and heat for farm animals. Most of the energy for muscular work thus comes from the carbohydrates in the food. It is

also shown in later chapters that the carbohydrates are the chief source of body fat and an important source of the fat in milk.

So far as is known, in ordinary rations the value of the carbohydrates in various feeds generally depends on the extent to which they are digested and on the net energy they furnish. Thus, the value per pound of starch and of the various sugars is usually about the same, while fiber has a much lower value, even for ruminants.

Especially for young animals, milk sugar (lactose) seems to increase the assimilation and use of calcium and phosphorus, probably because of its influence on the type of bacterial growth in the intestines. Lactose tends to produce an acid type of fermentation and to prevent putrefaction. However, too large a proportion of lactose, as when there is too much dried whey in a ration, may produce diarrhea. (**896**)

137. Molasses.—Molasses, consisting chiefly of sugars, may sometimes be very desirable in stock feeding, as it increases the palatability of feeds that might not otherwise be well-liked. For example, stock will clean up low-grade hay better if diluted molasses is sprinkled over it. It has been shown in the preceding chapter that the addition of a large amount of molasses to a ration may decrease its digestibility. (**103**)

The use and value of molasses for the various classes of stock are discussed in Chapter XXIII.

QUESTIONS

1. Is it generally dangerous to feed considerably more protein than needed?
2. Explain what is meant by an essential amino acid.
3. How can it be determined whether or not a certain amino acid is essential for a particular kind of animal?
4. What is known about differences in the amino acid requirements for different body functions?
5. Why are the requirements of ruminants and horses for protein much more simple than in the case of pigs or chickens?
6. What is meant by protein of good quality?
7. Describe how the protein in one feed can supplement that in another.
8. What is the effect of excessive heating on protein quality; of long storage of feed?
9. What is meant by the time factor in protein supplementation?
10. How can a table showing the percentage of the essential amino acids help in making up efficient rations for pigs and poultry?
11. Describe one method of measuring the nutritive value of protein.
12. What quality of protein is furnished by the cereal grains; by wheat bran?
13. What is the quality of protein in milk, meat, fish, and eggs; in meat scrap, tankage, and fish meal?
14. Discuss the quality of protein in the following: (a) Well-cooked soybean oil meal; (b) raw soybeans; (c) peanut oil meal; (d) peas; (e) beans.
15. What is the quality of the protein in: (a) Linseed meal; (b) cottonseed meal; (c) coconut oil meal; (d) yeast; (e) dried distillers solubles?
16. Discuss the quality of protein in good forage crops.
17. What is known about the quality of the protein in good grass pasture?
18. What is the quality of protein in legume forage for ruminants?
19. Compare the importance of quality of protein for cattle or sheep with its importance for swine or poultry.
20. What pure amino acid is sometimes used in supplementing rations for poultry?
21. Under what conditions and for what kinds of stock may the use of urea as a protein substitute be economical?
22. What are the functions of fat in the body?
23. What is known about the needs of farm animals for a minimum amount of fat?
24. Why is by-product animal fat often added to formula feeds or to alfalfa meal?
25. Does the fat of milk have special value?
26. Discuss the value and functions of various carbohydrates.
27. What special value may molasses have in a ration?

CHAPTER VI

MINERALS IN LIVESTOCK FEEDING

138. Importance of minerals.—It has long been known that common salt, calcium, and phosphorus are necessary for the health of animals, and even for life itself. However, as late as thirty years ago, the knowledge was very limited concerning the exact amounts required of these minerals, and but little was known about the need for any other minerals.

Since that time, outstanding discoveries have been made concerning the mineral nutrition of animals. It has been found that in some areas or under certain conditions disastrous results are produced by a previously unknown lack of one of the trace minerals—iodine, copper, iron, cobalt, or manganese. The effects of a deficiency of calcium, phosphorus, or salt for the various kinds of farm animals have also been studied in detail, and the requirements for these minerals carefully determined.

These discoveries have caused much popular interest in the subject of minerals and have led to extensive use of mineral supplements in stock feeding. (For simplicity, the common practice is followed in this volume of referring to mineral nutrients or mineral compounds as "minerals.")

Although decided deficiencies of other minerals may occur that must be corrected by the use of a suitable mineral supplement, common salt is the only mineral that must generally be added to usual rations for cattle and sheep. To avoid expenditures for unnecessary mineral supplements, it is therefore important that stockmen know definitely the conditions under which there may be a lack of other minerals, and also know how to correct any deficiency at minimum cost. The use of mineral supplements when they are not needed is not only a waste of money, but also may in some cases be actually injurious.

One of the chief purposes of this chapter is to show when mineral supplements should be provided for stock, and when none is needed, except common salt. Further information about the mineral needs of each class of stock is given in Part III. The amounts of calcium and phosphorus in various feeds are shown in Appendix Table I, so far as data are available, and the amounts of other important minerals in typical feeds are given in Appendix Table IV.

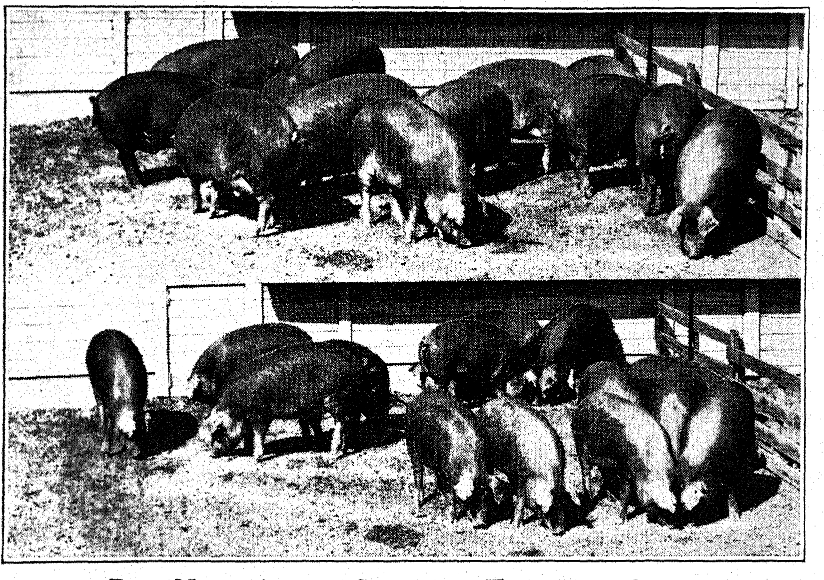
The amounts of calcium and phosphorus required by each class of the larger farm animals are stated in the Morrison feeding standards (Appendix Table III), and the mineral needs of poultry are shown in detail in Chapter XXXVI.

139. Functions of minerals.—Minerals have many vital functions in the body. First of all, the skeletons of vertebrate animals are composed chiefly of minerals (nearly all calcium and phosphorus). Minerals are also necessary constituents of the soft tissues and the fluids of the body. A few examples will serve to show how indispensable minerals are in the body. Phosphorus is a vital ingredient of the chief proteins in the nuclei, or life centers, of all body cells. It is also a part of certain other important proteins, such as the casein of milk. The phospholipids, which are phosphorus-containing fat-like substances, are essential parts of all living protoplasm. The power of the blood to carry oxygen is due to hemoglobin, the iron-protein compound in the red blood corpuscles.

The soluble mineral compounds in the blood and other body fluids are necessary to give these fluids their characteristic properties and to regulate the life processes. The acidity or alkalinity of the digestive juices is caused by mineral compounds. Thus, the acidity of the gastric juice in the stomach, which is neces-

sary for the action of the enzyme pepsin, is due to hydrochloric acid, formed from sodium chloride and other chlorides present in the blood. The osmotic pressure, needed for the transfer of nutrients and waste products through the cell walls, depends on mineral salts.

The maintenance of an approximately neutral reaction in body tissues, or the prevention of acidity or alkalinity, is due chiefly to a delicate adjustment of the mineral compounds in the body



PIGS NEED AMPLE SALT FOR EFFICIENT GAINS

Pigs supplied with salt in addition to a ration of corn plus soybean oil meal, alfalfa leaf meal, bone meal, and ground limestone, gained nearly twice as fast in Indiana experiments as those getting no salt. Upper lot: pigs supplied with salt. Lower lot: pigs getting no salt. (From Vestal, Indiana Station.)

fluids. A serious lack of calcium in the blood, such as occurs in milk fever of cows, causes convulsions and tetany.

For the various life processes, not only must there be sufficient supplies of the various essential minerals, but also there must not be a large excess of any of them. Thus, the regular beating of the heart depends on proper proportions of calcium and potassium in the blood. The kidneys are usually able to protect the animal against any excess of various minerals in the blood by excreting the excess in the urine. However, if the food continually furnishes an excessive amount of certain minerals, the body may be unable to keep the blood composition normal, and injury will result.

140. Sodium and chlorine; common salt.—Both sodium and chlorine are necessary for animal life, and farm animals usually do not secure enough of these two minerals in the feed they eat. To furnish these minerals, common salt (sodium chloride) should be supplied, except under unusual conditions.

Through recent investigations at certain experiment stations, partly financed by the Salt Producers Association, much new information has been gained concerning the requirements of farm animals for salt and for its two constituents, sodium and chlorine. These experiments have shown that at least in the case of dairy cows, sheep, and pigs, the chief deficiency in a ration made up of ordinary feeds, with no added salt, is sodium, rather than a lack of chlorine. The experiments dealing with the salt requirements of each kind of farm animals

are summarized in the respective chapters of Part III.

Cattle, sheep, horses, and other herbivorous animals (those that live chiefly on forage) need a somewhat greater proportion of salt in their rations than do swine or poultry, and show great hunger for salt when it is not supplied. Carnivora (flesh eating animals) secure sufficient salt in the flesh and blood they consume and therefore need no additional salt. If swine are fed meat scrap, tankage, or fish meal as the chief or only protein supplement, these feeds may supply enough salt. However, it is the safest plan to furnish them with salt even then.

The amount of salt needed may vary somewhat in different regions, depending on the salt content of the feeds grown there and on whether or not the water contains an appreciable amount of salt. Occasionally, in arid districts or very near the ocean where salt reaches the land from spray in the atmosphere, the forage, soil, or water may contain so much salt that there is no need of furnishing additional salt for livestock grazing there.

Salt may be provided in the form of loose salt, salt blocks, or lumps of rock salt, the choice depending on which form is cheapest or most convenient. An excellent method is to furnish a supply where the stock can take what they desire. They will not eat too much unless they have previously had an insufficient supply. They may then take so much at first as to cause indigestion, and therefore the amount should be limited at the start. For outdoor feeding in humid districts, placing the salt in suitable salt boxes will greatly reduce the wastage from weathering, especially if the boxes are protected from rain.

For dairy cows, 1 per cent of salt is generally included in the concentrate mixture, and then additional salt is provided so that they can take more if they wish. In the case of poultry, one-half per cent or less of salt is commonly included in the mash.

Salt stimulates the secretion of saliva and promotes the action of certain enzymes. It is an appetizer, as well as a nutrient, and animals may therefore consume more than they actually need. However, since salt is cheap, allowing them to take what they desire is wise.

Sodium and chlorine are important in maintaining the necessary osmotic pressure in the body cells, and sodium is the chief alkaline element concerned in maintaining neutrality in body tissues. Chlorine is required for forming the hydrochloric acid in the gastric juice. Blood is much richer in sodium and chlorine than in other minerals.

Sodium and chlorine are normally excreted chiefly in the urine. Also, sweat is high in these minerals. When the salt intake is large, the excess must be excreted in the urine, and about 5 gallons of urine must be produced for each pound of salt consumed.

When men do hard work at unusually high temperatures and sweat profusely, as in deep mines and furnace rooms, they suffer less from fatigue if they take salt tablets regularly or drink water containing a small amount of salt. This replaces the salt lost in the sweat. Similarly, it is important to provide plenty of salt for horses doing hard work in hot weather.

If animals receive insufficient salt, the body retains its supply tenaciously, and the excretion in the urine is greatly reduced. However, if the lack is severe and long continued, injury results. The digestibility of food is lessened, appetite is much decreased, growth declines, and reproduction may be impaired.

141. Consuming large amounts of salt.—Farm animals are not harmed by consuming considerably larger amounts of salt than they need. Advantage is taken of this fact in mixing salt with a protein supplement for cattle or sheep on the range, and then self-feeding the mixture to save labor, instead of hand-feeding the protein supplement each day. The percentage of salt in the mixture is regulated so that the stock will eat the needed amount of protein supplement, and no more. The experiments in which this method has been tested are summarized in Chapters XXVIII and XXX.

Surprisingly large amounts of salt

may be consumed without injury in this method. For example, beef cows have eaten over 2 lbs. of salt daily in such a mixture for long periods with no harm. In this method it is essential that the animals have access to plenty of water, conveniently available, so that they can get rid of the excess salt through the urine.

Salt poisoning of stock may occur, if animals have access to brine or unusually salty whey, when water is not readily available. A very large percentage of salt in the mash may kill poultry. For example, chicks were killed in one experiment when 5 per cent of salt was included in the ration.[1] On the other hand, in another test chickens grew normally on a ration having as much as 8 per cent salt.[2]

142. Calcium and phosphorus.—Farm animals are more apt to suffer from a lack of phosphorus or of calcium than of any of the other minerals except common salt. Calcium and phosphorus compounds make up about three-fourths of the mineral matter in the entire bodies of farm animals and over 90 per cent of that in their skeletons. Compounds of these minerals also form more than half the minerals in milk. Therefore liberal amounts of calcium and phosphorus are needed by growing animals, by those that are pregnant, and by those which are producing milk. Even for merely maintaining mature animals, sufficient amounts of these minerals must be provided to replace the daily losses from the body, or injury will finally result.

In order to assimilate and use the calcium and phosphorus in their food efficiently, animals must have sufficient vitamin D. As is shown in the next chapter, this may be furnished either in the feeds they eat or through the effect of sunlight or other light that contains ultraviolet rays. Also, the ratio, or proportion, between the amount of calcium and the amount of phosphorus in the ration should be within certain limits. A great excess of one of these minerals may be detrimental, even though the supply of the other is ample. The importance of this factor is discussed later.

There is now more apt to be a need of a calcium or phosphorus supplement in addition to usual rations than in early days. This is because of two factors. First, the supply of these minerals in the common feeds, especially in roughages, has decreased in the older farming districts, because the calcium and phosphorus content of the soil has been depleted. Second, the requirements of farm animals for these minerals have become much greater, as their rates of production of meat or milk have been increased through breeding and through improved and more intensive methods of feeding and management.

Under many conditions there is a plentiful supply of both these minerals in the rations for farm animals, without the addition of any special calcium or phosphorus supplements. On the other hand, a lack of one or both of these minerals may sometimes occur which lowers production or even causes serious injury. It is therefore highly important to know whether or not there are sufficient amounts of these minerals in any particular ration.

The requirements of the farm animals, except poultry, for calcium and phosphorus are stated in the Morrison feeding standards, and the requirements of poultry are shown in Chapter XXXVI. Specific information is also given in Part III as to whether or not various common rations are lacking in calcium or phosphorus, and recommendations are there made for the correction of any such deficiencies.

Stock require somewhat more calcium than phosphorus, because the amount of calcium in their bodies is much greater than of phosphorus. Also, milk contains slightly more calcium than phosphorus. In spite of these facts, there is less apt to be a lack of calcium than of phosphorus in the rations of cattle, sheep, or horses. This is because roughages generally make up a large part of the feed eaten by these animals, and most roughages contain much more calcium than phosphorus. Only when such animals are fed largely on grain and other concentrates or when the rough-

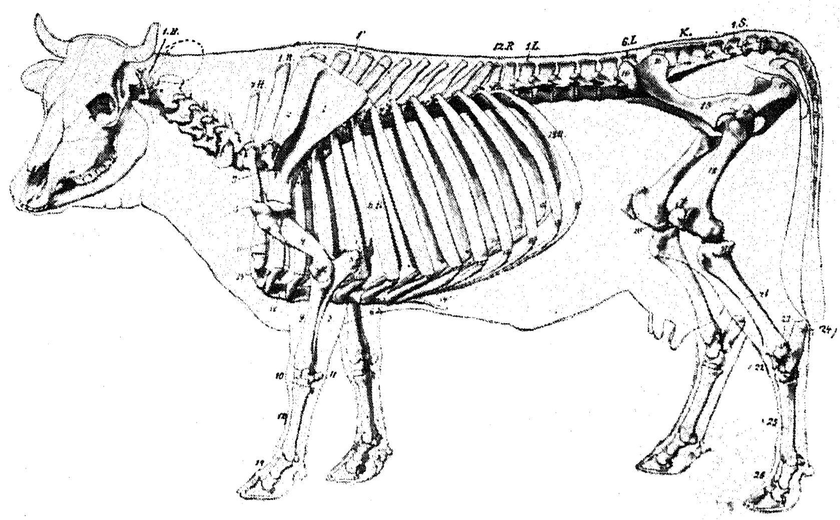
age is unusually poor, is there apt to be a lack of calcium.

The condition is, however, far different in the case of swine and poultry. They are commonly fed chiefly on grain and grain by-products, all of which are very low in calcium, but are fair or even high in phosphorus.

Also, poultry require much higher percentages of calcium and phosphorus in their rations than do other classes of stock, and the need for calcium for egg shell formation is particularly great. Both calcium and phosphorus supplements must therefore be added to most poultry rations.

Swine need somewhat greater percentages of calcium and phosphorus than do cattle or sheep. They generally need a calcium supplement, unless calcium-rich protein supplements, such as meat scrap, tankage, fish meal, or milk, are fed in sufficient amounts. Also, it is beneficial to add a phosphorus supplement to some common swine rations.

Young animals have much greater ability to absorb and use calcium than do older ones. It is shown later that in the case of very old animals, it may be difficult to prevent a loss of calcium from the body, even when they are fed a ration that would supply plenty for younger ones. (245) It is therefore important that aged animals have abundant calcium.



GROWING ANIMALS NEED ABUNDANT CALCIUM AND PHOSPHORUS

Over 90 per cent of the mineral matter in the skeleton consists of calcium and phosphorus. In certain rations the amounts of these minerals may be insufficient for health. (From Ellenberger.)

143. Composition and formation of bone.—The bones of mature animals contain about 26 per cent of mineral matter, 20 per cent of protein, 4 per cent of fat, and 50 per cent of water. Approximately 85 per cent of the mineral matter is calcium phosphate, 14 per cent calcium carbonate, and 1 per cent magnesium phosphate or carbonate.

The growth of bones in length occurs in a zone near the ends of the long bones. Here the mineral compounds are deposited in a temporary zone of cartilage. Bone increases in diameter by formation of bone under the periosteum, the membrane which covers the bones.

The chief strength of a long bone is due to the dense, compact bone in the outer shaft. Inside the bone, especially near the ends, is spongy bone, made up of a lace-like bony network (called "trabeculae"). This spongy bone serves as a reserve store of calcium and phos-

phorus that can readily be drawn upon when the supply in the feed is insufficient to meet the needs. When the supply is more liberal or the needs are less, the store can then be replenished. It is shown in Chapter XXV that a high-producing cow normally draws on this store of minerals in her skeleton at the height of milk production. (1037)

Unless the draft on the calcium and phosphorus lasts too long, the animal is not injured at all by this process. However, if the shortage continues unduly long, the supply in the spongy bone will be exhausted, and calcium and phosphorus will be drawn from the shafts and other supporting parts of the bones. This will weaken them and may produce serious injury.

144. Calcium and phosphorus content of feeds.—Because of the importance of calcium and phosphorus, the author has compiled the available data concerning the amounts of these minerals in various feeds. These averages are given in Appendix Table I. It will be noted that such information is still limited, in comparison with the data for the content of protein, fat, fiber, nitrogen-free extract and total mineral matter in feeds.

In using these figures it must be remembered that the amounts of these minerals in any particular lot of feed, especially of a roughage, may differ considerably from the average. When grown on soil low in available phosphorus or in calcium, roughages will generally contain decidedly less of the mineral than when grown on fertile soil. At early stages of growth, forage plants contain much more calcium and phosphorus, on the dry basis, than at later stages.

145. Calcium content of roughages.—One of the most important facts concerning the calcium content of feeds is that legume hays and all other legume forages except legume straw are very rich in calcium. Alfalfa hay of average quality has 1.47 per cent calcium; red clover hay, 1.28 per cent; and soybean hay, 1.10 per cent. Though the calcium content of legume forage is influenced to some extent by the amount of this mineral in the soil, one can always safely count on its being relatively rich in calcium. If the soil is too deficient in calcium, legume crops will not grow.

Non-legume roughage in general contains much less calcium than that from legumes, and if grown on soil deficient in calcium, such roughage may be considerably lower in this mineral than indicated by the average figures. Timothy hay of average quality has 0.35 per cent calcium; good-quality hay from mixed grasses, 0.48 per cent; and dry corn stover, 0.54 per cent.

Grass that is mature, and especially that which is weathered, is lower in calcium than immature grass. However, there is generally less difference in the calcium content than in the content of phosphorus. Even mature, weathered grass generally has a fair content of calcium, while the phosphorus may be seriously low.

Cereal straw is slightly lower than grass hay in calcium content. Silage from corn or the sorghums contains about as much calcium, on the dry basis, as does hay from the grasses. Roots and tubers are generally low in calcium.

146. Calcium content of concentrates.—All of the cereal grains are exceedingly low in calcium, the content ranging from only 0.02 per cent in corn to 0.09 per cent in oats. None of the by-products of the grains is rich in calcium, and wheat bran, wheat middlings, corn gluten meal, and corn distillers dried grains are all low. Most oil meals are low to fair in calcium, peanut oil meal having 0.16 per cent, soybean oil meal 0.27 per cent, and linseed meal 0.37 per cent.

In the process of manufacture lime is added to certain by-products, thus increasing the calcium content. For this reason dried citrus pulp has 1.98 per cent calcium, dried beet pulp 0.69 per cent, and corn gluten feed 0.41 per cent.

Milk and the animal by-products that contain bone, such as meat scrap, tankage, and fish meal, are rich in calcium. On the dry basis milk has about as much calcium as does legume hay,

dried skimmilk having 1.28 per cent. Fish meal has 5.36 per cent calcium, and meat scrap of the 50-per-cent-protein grade contains so much bone that it has 10.67 per cent calcium.

147. Phosphorus content of roughages.—There are striking differences in the content of phosphorus and of calcium in various feeds. While legume forage is rich in calcium, none of the roughages is rich in phosphorus. The phosphorus content of various hays usually ranges from 0.15 per cent or even less, up to 0.30 per cent. Legume hay contains but little more phosphorus than grass hay of similar quality.

Early in their growth, grasses and legumes have a much larger percentage of phosphorus on the dry basis than at the hay stage. Thus, mixed pasture grasses and clovers from well-grazed, fertile pastures have 0.58 per cent phosphorus on the air-dry basis. Fodder and silage from corn or the sorghums generally have slightly less phosphorus, on the dry basis, than grass hay. The stover from these crops, the straws from the small grains, and likewise such feeds as cottonseed hulls and flax straw are very low in phosphorus. On the dry basis some roots and tubers are slightly higher in phosphorus than the hay crops, while sweet potatoes are low.

A decided phosphorus deficiency of the soil reduces the phosphorus content of forage even more than a lack of calcium lowers the calcium content. Pasturage, hay, or other forage from land poor in phosphorus may be so low in the mineral that it produces serious phosphorus deficiency in stock, if it is the only source of phosphorus.

Also, the phosphorus content of the grasses is greatly lowered as the plants mature and especially as the dried plants become weathered. Mature, weathered range forage is therefore often very low in phosphorus.

148. Phosphorus content of concentrates.—The cereal grains contain a fair amount of phosphorus, differing decidedly in this respect from their very low content of calcium. The percentage of phosphorus ranges from about 0.27 per cent in corn grain to 0.39 per cent in wheat.

A very important fact is that most of the protein-rich by-product concentrates of plant origin are much higher in phosphorus than are the grains or the roughages. Wheat bran is especially rich in phosphorus, containing 1.29 per cent. Standard wheat middlings have 0.93 per cent; cottonseed meal of the usual grades, 0.89 to 1.19 per cent; and linseed meal, 0.86 per cent. Wheat flour middlings have less phosphorus than standard middlings, and wheat red dog flour contains still less.

The protein-rich legume seeds are medium in phosphorus, soybeans having 0.59 per cent; field peas, 0.50 per cent; and cowpeas, 0.46 per cent. Soybean oil meal contains 0.63 per cent phosphorus and peanut oil meal 0.54 per cent. Corn gluten meal is relatively low in phosphorus for a protein-rich concentrate, while corn gluten feed has an average of 0.80 per cent.

Milk is nearly as rich in phosphorus as it is in calcium, dried skimmilk having 1.04 per cent phosphorus, for example. Because of the bone they contain, meat scrap, tankage, and fish meal are very high in phosphorus as well as being rich in calcium. Thus, meat-and-bone scrap of the 50-per-cent-protein grade contains 5.27 per cent phosphorus, and fish meal 3.42 per cent. On the other hand, dried blood is relatively low in both phosphorus and calcium, having 0.25 per cent phosphorus and 0.32 per cent calcium.

149. When do lacks of calcium occur?—Certain general conclusions can be drawn from these data on the calcium and phosphorus content of various classes of feeds. It is shown in Part III that dairy cattle, beef cattle, sheep, and horses do not need more than 0.2 to 0.3 per cent of calcium in their rations on the air-dry basis, except in the case of very young animals.

Legume forage, no matter whether it is hay, silage, or pasturage, usually has about 1.0 per cent or more of calcium on the air-dry basis. Therefore when legume forage forms any important part

of the ration for cattle, sheep, or horses, there will ordinarily be an abundance of calcium. Even when no legume roughage is fed to these classes of stock, there will usually be no deficiency of calcium unless the roughage is grown on soil very low in calcium or unless they are fed largely on grain and other concentrates, with only a limited amount of roughage.

Although good dairy cows need large amounts of calcium for the milk they produce, it is shown in Chapter XXV that generally there is not apt to be a deficiency of calcium in their rations when they are fed good roughage, even if none of it is legume forage. (**1036**) However, when no legume roughage whatsoever is fed to dairy cows, it is probably wise to furnish additional calcium as insurance against any possible lack, unless the non-legume roughage comes from soil well supplied with calcium.

It is shown in Chapters XXVIII and XXX that when young cattle or lambs are fattened on liberal amounts of grain, with non-legume roughage and such protein supplements as soybean oil meal or linseed meal, there may be a decided lack of calcium in the ration. This is because they do not eat enough roughage to meet their calcium requirements. In such cases there will generally be a great benefit in rate and economy of gain from feeding a calcium supplement, such as ground limestone.

If the animals have been raised previous to the fattening period in an area where the forage is high in calcium, they may have in their bodies a sufficient store of the mineral to meet their needs during the usual fattening period. They may then show little or no benefit from the addition of a calcium supplement.

There is an entirely different situation with reference to the need for additional calcium in the rations of swine and poultry. For the reasons stated previously in this chapter, a calcium supplement is needed in most poultry rations, and swine also generally need additional calcium. (**142**)

Disastrous results may be caused by stock eating too much of certain plants that contain considerable oxalic acid or soluble salts of oxalic acid. On being absorbed by an animal, these react with the calcium in the body to form insoluble calcium oxalate, and the animal may die from the resulting extreme calcium deficiency. This is the cause of the severe losses from halogeton poisoning on certain western range areas. (**675**)

150. When are there deficiencies of phosphorus?—Since the cereal grains are fair in phosphorus content and most protein-rich concentrates are rich in this mineral, there will generally be no lack of phosphorus when stock are fed a considerable proportion of these feeds in a well-balanced ration. However, when the ration is balanced only by protein supplements not rich in phosphorus, there may be a lack.

The phosphorus supply for beef cattle, sheep, and horses will be ample even when they are fed entirely on roughage, if the forage has been grown on soil reasonably well supplied with the mineral. On the other hand, there may be a serious deficiency of phosphorus if stock are fed chiefly on phosphorus-poor forage, without any supplement that is high in this essential.

There are large areas in this and other countries where the forage is so deficient in phosphorus that serious results are produced in livestock unless this lack is corrected. In these areas the soil is so lacking in available phosphorus that the forage grown on it is very low in the mineral. As has been pointed out in Chapter IV, the percentage of phosphorus in grain and other seeds is affected much less by a deficiency of phosphorus in the soil, but the yield may be reduced severely. (**99**)

Fertilization with superphosphate or other phosphorus fertilizers not only greatly increases the yields of crops in such areas, but also generally produces feeds of normal phosphorus content and therefore prevents injury to stock from a lack of the mineral. Wherever fertilization of the land is not practicable, as on range areas, trouble from phosphorus deficiency may be prevented by supplying

bone meal or some other safe phosphorus supplement.

Because of the higher phosphorus requirements of dairy cows, a ration of roughage alone or even of roughage and farm grain is apt to be deficient in phosphorus. (**1035**) Therefore, unless one is sure that the hay or other roughage has a good content of phosphorus, a phosphorus supplement should be added to such rations.

When meat scrap, tankage, or fish meal are used as the only or the chief protein supplements in rations for swine or poultry, there will generally be no need of adding a phosphorus supplement. On the other hand, a phosphorus supplement should be used when the ration is balanced largely with such a protein supplement as soybean oil meal, which is not very high in phosphorus.

151. Value of phosphorus in various feeds.—In some cases it is necessary to consider not only the amounts of phosphorus in various feeds, but also the form in which the phosphorus is present. A large part of the phosphorus in seeds and their by-products is in the form of phytin, an organic phosphorus compound. Investigations have shown that the phosphorus of phytin is not so well assimilated by certain animals as phosphorus in other forms. This is especially the case with poultry. As shown in Chapter XXXVI, in poultry rations a certain proportion of the phosphorus must therefore be supplied in non-phytin form, such as bone meal or other suitable phosphorus supplements. Hens can use phytin phosphorus somewhat better than can chicks. Recent experiments mentioned in Chapter XXXIV indicate that pigs utilize phytin phosphorus less efficiently than non-phytin phosphorus.

The assimilation of phytin phosphorus is improved when the ration has a plentiful amount of vitamin D. It may also be increased when the ration contains natural, unheated roughages, for these contain an enzyme which splits off the phosphorus from the phytin.

Experiments have shown that ruminants can use phytin phosphorus satisfactorily. The phosphorus in roughages is generally well utilized by stock.

152. Calcium-phosphorus ratio.—It has been mentioned previously that not only must animals receive adequate amounts of calcium and phosphorus, but also there should be a suitable proportion, or ratio, between the amounts of these two minerals. If there is a great excess of calcium or of phosphorus, detrimental effects may be produced, even when there is an amount of the other mineral that would be adequate under usual conditions. Also, less vitamin D is needed in the ration when there is a desirable calcium-phosphorus ratio.

Apparently, little attention need be given to the ratio between the amounts of calcium and phosphorus in feeding cattle or sheep, if there is a plentiful supply of each mineral. However, recent experiments with beef calves have shown that when there is a slight shortage of phosphorus in the ration, adding a calcium supplement that is not needed may increase the phosphorus deficiency.[3]

With an ample amount of both calcium and phosphorus, the results have been satisfactory when cattle have been fed rations having calcium-phosphorus ratios ranging all the way from more than 6 to 1 down to 0.6 to 1.[4] (A ratio of 6 parts of calcium to 1 of phosphorus is written as a ratio of 6 : 1.) In a recent New Hampshire investigation, however, adding an excessive amount of ground limestone (0.2 lb. per head daily) to a ration for dairy heifers slightly decreased the digestibility.[5] Adding half as much limestone did not have this undesirable effect.

For swine, rations having calcium-phosphorus ratios between 1.1 : 1 and 1.5 : 1 seem to be most satisfactory,[6] and for chicks a calcium-phosphorus ratio of about 1.5 : 1.[7]

153. Effects of phosphorus or calcium deficiency; rickets.—A decided deficiency of phosphorus or calcium, or a failure to utilize these minerals because of a lack of vitamin D, will cause rickets in growing animals and will also produce serious trouble in mature animals.

Even a moderate lack may result in a weak skeleton that cannot withstand the usual strains and shocks.

The term *rickets* is commonly used for the disease produced in young animals by a lack of calcium, phosphorus, or vitamin D. (Sometimes the term is used also for similar diseases in mature animals.)

In rickets the blood becomes deficient in phosphorus or calcium or in both of these minerals. As a result, normal amounts of phosphorus and calcium are not deposited in the growing bones. The bones are therefore weak and are readily broken or fractured. In an attempt to overcome the weakness, the long bones become abnormally large at the ends, where the growth takes place. Thus, characteristic enlargement, or "beading," often results at the ends of the ribs. If rickets develops at an early age, the legs may become decidedly deformed.

Among the larger farm animals, rickets occurs most frequently in young dairy cattle and in pigs. The methods of preventing this trouble in these animals are therefore discussed fully in Chapters XXVII and XXXIV.

In young cattle characteristic symptoms of rickets are stiffness, swollen joints, bent knees, and an arching of the back, except immediately at the rear of the shoulders, where there is often a sag. The animal frequently stands humped up with middle drawn up and is often easily excited and may have attacks of fits. Respiration is rapid, and the animal becomes exhausted from slight exertion. A depraved appetite may develop, as shown by the chewing of bones, wood, or hair. In severe cases the animal may show a decided lack of appetite, especially for roughage.

The most marked symptom of rickets in pigs is stiffness of the legs. This is usually accompanied by a general unthrifty appearance and failure to make good gains in weight. Eventually, paralysis of the hind legs often occurs. This is due, at least in certain cases, to a fracture of one of the vertebrae and the resulting crushing or constriction of the spinal cord.

If the disease has not advanced too far, the animal will usually recover when supplements are added to the ration that furnish liberal amounts of vitamin D, calcium, and phosphorus. However, recovery may be slow if it has reached the stage where there is a marked lack of appetite. Also, it may be impossible to overcome malformations of the skeleton produced by the disease.

CALVES SUFFERING FROM RICKETS

The calf on the left has a mild case of rickets. It is beginning to show the characteristic arching of the back, swollen knees, and stiffness. Note the tendency to develop long toes. The calf on the right has a very bad case of rickets. Note the crippled condition, bent and swollen knees, swollen hocks, and badly arched back. (From Huffman, Michigan Station.)

154. Phosphorus or calcium deficiency in mature animals.—In the case of mature animals a deficiency of phosphorus or calcium or a lack of vitamin D produces mineral-deficiency diseases that are somewhat different from rickets.

Phosphorus and calcium are with-

drawn from the bones to meet the needs for these minerals by the body. The store of these minerals in the spongy part of the bone will be drawn on first. If the deficiency is not too serious or continued too long, the strength of the skeleton will not be injured. However, if the withdrawal continues, phosphorus and calcium will be taken from the shafts and other structural parts of the bones. As a result, the bones become porous and weak, and are easily broken. The animals also often become lame or stiff, because of injury to the joints.

The term *osteomalacia* is most frequently used for the deficiency diseases in mature animals caused by a lack of phosphorus or calcium or a deficiency of vitamin D. Other names given to these troubles are pica, stiffs, and osteoporosis. Sometimes these diseases are included under the term rickets, but this term is best used only for the similar disease in growing animals.

If breeding females are fed rations seriously deficient in phosphorus or calcium, the body of the mother does its utmost to protect the young against the lack by withdrawing the mineral from her skeleton. In extreme cases, normal reproduction may be prevented and the young may be born weak or even dead. This is much more apt to occur in the case of brood sows than with herbivora, for sows fed on only grain and grain by-products receive a ration that is disastrously deficient in calcium.

155. Effects of phosphorus deficiency.—One of the first symptoms of a deficiency of phosphorus is a lack of appetite and a run-down, unthrifty appearance.[8] Animals that are still growing will fail to make normal gains, and those producing milk will drop off greatly in yield. A continued lack of phosphorus will generally cause a depraved appetite, and the animals will gnaw bones, wood, or other objects, or eat dirt in an instinctive effort to secure the needed mineral. In severe cases of phosphorus deficiency the animals sometimes no longer show a depraved appetite, but are listless and have little desire for food.

Heavy death losses of cattle from botulism have occurred on phosphorus-deficient range pasture, due to the eating of decayed bones or flesh in which the botulinus toxin has been produced.

A long-continued phosphorus deficiency will often cause stiffness of the joints, and the bones may also become fragile and easily broken. A severe lack of phosphorus in breeding females may cause weak or dead offspring. The milk yield may also be so low that the mother is unable to nurse her young properly. High-producing cows and young stock are usually affected most by the deficiency, because of their greater needs for the mineral. In phosphorus-deficient areas cows frequently fail to come in heat regularly and often do not calve more than once in two years.

In cases of phosphorus deficiency, animals not only have poor appetites and eat less feed than normal, but also they utilize poorly that which they do consume.[9] In phosphorus deficiency, the digestibility of the feed is not appreciably reduced, but the digested nutrients are utilized inefficiently. In cattle, but not in sheep, the conversion of carotene into vitamin A in the body may apparently be interfered with.

156. Effects of calcium deficiency.—It has been shown previously in this chapter that cattle, sheep, or horses are not apt to lack calcium when good roughage forms a large part of their rations. (149) However, in a few areas the soil is so deficient in calcium that serious trouble occurs unless a calcium supplement is provided. (1036) Injury from calcium lack may also result if dairy cows are fed only a small quantity of poor-quality grass hay with a concentrate mixture having no added calcium supplement.

While dairy cows suffering from phosphorus deficiency are commonly thin and run-down in condition, those affected by a lack of calcium may be in good flesh if fed liberally on concentrates. However, their milk yield may be greatly reduced, and their bones may break without any unusual strain or shock.

Because of the deficiency of calcium in all the grains, care is necessary to make sure that swine and poultry are provided with plenty of this mineral. It is shown in Chapter XXXIV that a lack of calcium in the rations of brood sows may cause reproductive failure. The serious effects of a deficiency of calcium upon hens are discussed in Chapter XXXVI.

157. Calcium supplements.—When a ration is fed that is deficient in calcium, in phosphorus, or in both of these minerals, the lack should be corrected by the use of a suitable mineral supplement. In deciding what supplement to use, one should first determine which mineral is lacking. If the ration is deficient only in calcium and has plenty of phosphorus, it is uneconomical to use a supplement like bone meal, which furnishes both of these minerals. Such supplements cost much more than ground limestone or other calcium supplements. Also, if there is already plenty of phosphorus in the ration, it may be detrimental to add considerably more.

Ground limestone, which is mostly calcium carbonate, is the most commonly-used calcium supplement. This is generally cheap and is readily available in most areas. *High-calcium limestone*, or calcitic limestone, is to be preferred as a calcium supplement, for the value depends on the actual amount of calcium present. Such limestone has about 38.5 per cent of calcium. Sometimes "mineralized limestones," to which small amounts of such minerals as manganese or iodine have been added, are sold at prices that are extremely high, in comparison with ordinary limestone, considering the actual amounts of added minerals.

Dolomitic limestone, which contains considerable magnesium carbonate, is a fairly satisfactory calcium supplement, except for poultry. In Ohio tests the use of dolomitic limestone in place of high-calcium limestone lowered the egg production and tended to produce eggs with weak or thin shells.[10] For other stock dolomitic limestone has been equal in some experiments to high-calcium limestone, when fed at an equal calcium level, but in other tests it has not produced as good results.[11]

Ground oyster shell is an excellent calcium supplement and is very popular for poultry.[12] It contains approximately as much calcium as high-calcium limestone. Ground clam shell,[13] mussel shell,[14] coquina shell,[15] and coral[16] are also satisfactory calcium supplements.

Marl is satisfactory as a calcium supplement when it does not contain too large a proportion of clay or sand. Its value per ton will obviously depend on the amount of calcium it supplies.

Precipitated calcium carbonate, a by-product from soap and sugar factories, is sometimes available for use as a mineral supplement and is entirely satisfactory for the purpose.

Wood ashes contain about two-thirds as much calcium as does ground limestone and may be used in place of it as a calcium supplement, when available on the farm.

Gypsum supplies calcium in the form of calcium sulfate instead of calcium carbonate, as in limestone and the other calcium supplements that have been mentioned. It is apparently satisfactory for use as a calcium supplement in stock feeding, except for laying poultry.[17] To meet the heavy demand for calcium in egg-shell formation, calcium in carbonate form, as in limestone or in oyster shell, is much superior to that in gypsum or in bone meal or other phosphate sources.[18]

Basic slag was a satisfactory calcium supplement for pigs in Mississippi tests.[19]

Unslaked lime or *water-slaked lime* (hydrated lime) should not be fed to stock, because of the caustic nature of these forms of lime.

158. Phosphorus supplements.—In using a phosphorus supplement for livestock feeding, it is necessary to see that the product does not have a dangerous amount of fluorine. As is explained later, if rations contain more than certain very small amounts of fluorine, livestock are injured. (168–169)

Bone meal and products made from

bone are entirely safe, as they have only a very small amount of fluorine. On the other hand, phosphates of rock origin generally contain dangerous amounts of fluorine unless they have been thoroughly defluorinated, or specially treated at a high temperature to remove most of the fluorine.

The common phosphorus supplements supply calcium as well as phosphorus, bone meals and spent bone black having about twice as much calcium as phosphorus.

Information is given in Part III on the relative values of the different phosphorus supplements for the various classes of stock, so far as data are available.

159. Steamed bone meal.—Steamed bone meal, often called merely "bone meal," is the most common phosphorus supplement for stock feeding. It contains an average of 30.14 per cent calcium and 14.53 per cent phosphorus, with 7.5 per cent protein and 1.2 per cent fat. If solvent-extracted, the average fat content is only 0.4 per cent.

In the production of steamed bone meal for feeding purposes, fresh bones of suitable quality are cooked under steam pressure very thoroughly. This extracts most of the protein and fat, which are used for other purposes. The residue is pressed and dried, and then ground.

Raw material of much better quality should be used in making bone meal for stock feeding than for fertilizer bone meal. For feeding, only bone meal should be bought that has definitely been made for this purpose and that has been so prepared that it is entirely free from any disease-producing organisms. Fertilizer bone meal often has a rank, disagreeable smell, differing decidedly from good-quality steamed bone meal.

Special steamed bone meal is similar to ordinary bone meal, except that it is produced in the manufacture of gelatin and glue from selected bone. It commonly has a trifle more calcium and phosphorus and a little less protein than does steamed bone meal. It has very little odor and is nearly white.

160. Cooked bone meal.—This by-product, formerly called raw bone meal, is not uncooked, but is thoroughly cooked in open kettles, instead of under steam pressure, as in the making of steamed bone meal. Because of the lower temperature, the protein is removed less completely, and cooked bone meal is therefore lower in phosphorus and calcium. It has an average of 26.0 per cent protein, 5.0 per cent fat, 22.96 per cent calcium and 10.25 per cent phosphorus. Cooked bone meal is sometimes ground more coarsely than steamed bone meal and screened into various sizes for poultry of different ages.

161. Spent bone black, or bone char.—Bone black is a granular product made by charring bone in closed retorts and grinding it coarsely. It is employed especially for clarifying and decolorizing the sirup in the manufacture of cane or beet sugar and in making table sirups. After the bone black has once been used and has taken up organic impurities, it is re-charred and used again. Finally, it becomes too powdery for further use, and is then dried and sold as *spent bone black*, or bone char, for stock feeding or for fertilizer.

Though black in color, spent bone black may have nearly as much phosphorus and calcium as steamed bone meal. It may be used in the same manner as steamed bone meal in stock feeding.

162. Rock phosphate; phosphorized limestone.—Most *rock phosphate* (sometimes called "lime phosphate") contains 3.25 to 4 per cent of fluorine. Experiments have proved that this high flourine content makes it unsafe for feeding to livestock as a phosphorus supplement for any long period, except possibly as part of the phosphorus supplements for poultry.

The rock phosphate from a few areas, especially the West Indian island of Curacao, generally has a much lower amount of fluorine. In using such phosphate for feeding, one should be sure that the level of fluorine is safe.

Phosphorized limestone is also unsafe for continued feeding to livestock.

It is part way between limestone and rock phosphate in chemical composition. Though the percentage of fluorine is lower than in rock phosphate, the proportion between the amounts of phosphorus and of fluorine is nearly the same as in rock phosphate. Therefore, if enough phosphorized limestone is fed to supply a certain amount of phosphorus, the ration will have nearly as much fluorine as though rock phosphate had been used.

In an instance which came under the observation of the author, disastrous results were produced in a dairy herd which, according to the owner, had been fed phosphorized limestone as a mineral supplement for 3 to 4 years. This had been done in a mistaken and vain effort to eradicate brucellosis, or Bang's disease, by the use of a mineral supplement.

163. Soft phosphate with colloidal clay, or colloidal phosphate.—This product is nothing but a mixture of fine particles of rock phosphate and clay. It is the fine material that is washed out of pebble rock phosphate in preparing the rock for crushing. Formerly the material was wasted, but it now is sold as a phosphate fertilizer and sometimes as a mineral supplement for livestock. It has about 18 per cent calcium and only 9 per cent phosphorus. In proportion to the content of phosphorus, it has nearly as much fluorine as does rock phosphate, and is therefore not safe for continued feeding.

In certain experiments with chicks and pigs, summarized in Part III, soft phosphate with colloidal clay has not been a satisfactory phosphorus supplement.

164. Superphosphate.—In the manufacture for fertilizer of superphosphate from rock phosphate, most of the fluorine is not removed. Therefore, superphosphate should not be used for feeding to livestock over any long period. For example, in a New York test with chicks superphosphate produced satisfactory results for 2 months, but by the end of 10 months over half of the chickens fed superphosphate had died.[20] Those that lived had grown much slower than others fed bone meal.

165. Defluorinated phosphates.—During the serious shortage of steamed bone meal in World War II, methods were developed for removing nearly all the fluorine from rock phosphate to produce defluorinated phosphate. According to the definition of the Association of American Feed Control Officials, defluorinated phosphate must not contain more than 1 part of fluorine to each 100 parts of phosphorus.[21] Such defluorinated phosphate is an entirely safe substitute for bone meal. It may be somewhat less palatable than bone meal.

The availability of the phosphorus and calcium in the defluorinated phosphates now made in this country is nearly equal to that in bone meal, while the phosphorus in certain of the products made earlier was much less available.[22]

166. Dicalcium phosphate; monocalcium phosphate; tricalcium phosphate.—*Dicalcium phosphate,* an excellent phosphorus supplement with a safe level of fluorine, is usually made from rock phosphate or phosphoric acid, but some is made from bones. It has 18 per cent or more of phosphorus, in comparison with 14.5 per cent for bone meal. Per pound of phosphorus, dicalcium phosphate equals bone meal as a phosphorus supplement.[23]

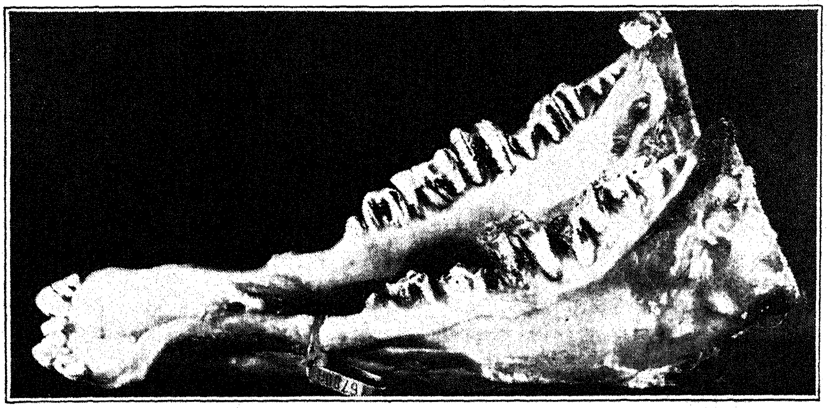
Monocalcium phosphate is a similar product, except that it has more phosphorus and much less calcium. *Tricalcium phosphate,* on the other hand has more calcium than does dicalcium phosphate.

167. Soluble phosphate added to water; phosphoric acid.—In areas where the salt content of the forage is higher than usual, livestock on pasture may consume but little common salt. When phosphorus supplements are mixed with salt, they may then not eat the desired amount of the mixture, and the phosphates are often not palatable when fed alone. Under such conditions, sometimes sodium phosphate or another soluble phosphate is added to the drinking water in the proper amount.[24]

In a recent Kansas test liquid phos-

phoric acid, added to molasses, was a satisfactory phosphorus supplement for beef cattle or sheep.[25] As phosphoric acid is corrosive, the small amount needed must be carefully mixed with suitable feeds.

168. Poisonous effects of fluorine.—Traces of the mineral fluorine are apparently needed by animals for the development of teeth of good quality, and these traces are amply supplied by all ordinary rations. In livestock feeding, we are concerned only with the poisonous effects of fluorine when dangerous amounts are consumed.



FLUORINE IN CERTAIN ROCK PRODUCTS MAY POISON STOCK

Jaw bone and teeth of cow which had been fed a mineral supplement containing fluorine for three years. The teeth were worn down to such an extent that the cow was unable to chew her feed normally. In spite of liberal feeding she became a pitiful wreck. (From Udall, New York State Veterinary College, Cornell University.)

Not only is fluorine a violent poison when taken into the body in any considerable amount, but it is also a cumulative poison. Even very small amounts have a poisonous effect if steadily consumed over a long time. The chief effect is upon the teeth and bones. The teeth have faulty enamel and are so soft that they wear down so much that the animals are unable to chew their food. In some cases the teeth are worn down to the pulp cavities and are so sensitive that the animals will not drink cold water, because of the pain, but lap it with the tongue, like cats or dogs. The bones become soft and are often enlarged, and the animals may become lame and have difficulty in walking.

In addition to these effects, animals suffering from fluorine poisoning may have poor appetites, and sometimes serious diarrhea. Young animals fail to gain normally, older ones lose weight, and milk production is much decreased.

Serious fluorine poisoning of stock, especially cattle, has occurred in a few areas where the water or soil was unusually high in fluorine, and also in the vicinity of certain smelters or factories where fluorine-containing flue gases have contaminated the soil and forage.

Several experiments have been conducted to determine the effects upon different classes of stock of rations containing various amounts of fluorine, the most extensive being the studies of Hobbs and associates at the Tennessee Station.[26] In the Tennessee experiments the teeth of cattle became worn and eroded when the animals were fed continuously rations containing 0.0037 per cent (37 parts per million) or more of fluorine.[27] Even less caused marked staining of the teeth. In these studies the injurious effect of fluorine was decreased if 0.1 to 0.5 per cent of aluminum sul-

fate or aluminum chloride was included in the ration.

Sheep or swine are not injured by fluorine unless the level is higher than would be detrimental to cattle, and poultry are still less susceptible to fluorine toxicity.

169. Safe levels of fluorine in rations.—Since fluorine is a cumulative poison, the amount that will be safe in a ration for any class of stock will depend on how long the feeding of the supplement is continued. Thus, in Wisconsin experiments with dairy cows, including 0.6 per cent of rock phosphate in the concentrate mixture produced marked poisonous effects only after 3 years of continuous feeding.[28] Then the results were very injurious.

The Committee on Animal Nutrition of the National Research Council has recently recommended that total rations should not contain more than the following percentages of fluorine from a rock source: Dairy cows, 0.006–0.010; beef cows, 0.0065–0.010; sheep and swine, 0.010–0.020; and chickens, 0.030–0.040.[29]

If a supplement containing fluorine, such as rock phosphate, is fed for only a short period, a somewhat higher level of fluorine is not injurious.

Total rations should not have more than the following percentages of fluorine in soluble compounds, which are more readily absorbed: Dairy cows, 0.003; beef cows, 0.004–0.005; sheep and swine, 0.007–0.010; chickens, 0.015–0.030; and turkeys, 0.030–0.040.

The Association of American Feed Control Officials has adopted the following tentative regulation for any mineral or mineral mixture: "The fluorine content of any mineral or mineral mixture which is to be used directly for the feeding of domestic animals shall not exceed 0.30 per cent for cattle; 0.35 per cent for sheep; 0.45 per cent for swine; and 0.60 per cent for poultry." [21]

In using a phosphorus supplement of rock origin or a mineral mixture containing such a product, one should note the guarantee of the manufacturer concerning the fluorine content. He should be sure that the fluorine content of the total ration fed does not exceed safe limits.

Bone meal contains about 0.03 to 0.04 per cent of fluorine, an amount that is entirely safe when the usual amount of bone meal is fed as a phosphorus supplement.

The application of phosphate fertilizers in ordinary amounts for many years does not apparently increase the fluorine content of forages to a dangerous level.[30]

170. Iodine; goiter in farm animals.—Iodine is necessary for animals, because the rate of metabolism of the body is controlled through the action of an iodine-containing hormone, called thyroxine, which is secreted by the thyroid gland in the neck. If an animal does not secure enough iodine in its food to make a normal amount of this compound, the thyroid gland may enlarge in an attempt to make sufficient of it, and the ordinary type of goiter results.

Only very small traces of iodine are needed by animals, and the bodies of mature animals have less than 1 part of iodine in 3 million parts of body weight. In the case of farm animals a deficiency of iodine is apt to cause goiter only in the new-born young. Older farm animals rarely show any symptoms of a lack of this mineral.

It is now well known that the soil and water in certain areas of this and other countries are so deficient in iodine that additional iodine must be supplied to prevent goiter in man or in livestock. In other regions the iodine supply is ample, and there is no benefit whatsoever from furnishing additional iodine. In the United States the chief iodine-deficient areas are in the Great Lakes region and westward toward the Pacific Coast.

Generally, iodine deficient areas are found only in interior districts, and the iodine supply is ample in most sea-coast regions. This is because sea water is rich in iodine. Ocean spray carried into the air evaporates, and the sea-salt dust is brought inland by wind.

Before the method of prevention was discovered, there were heavy losses

of new-born pigs, lambs, kids, calves, and foals in iodine-deficient areas, because of goiter. The young thus affected are born dead or weak, the losses being especially severe in the case of pigs and lambs. Such pigs usually are practically hairless, and the disease in swine is often called "hairless pigs." The pigs have thick, pulpy skin and large necks, and seem unusually large and fat because of a bloated condition. In lambs and calves affected with goiter, the enlarged thyroid gland is readily seen. In foals there is seldom a visible goiter, the only symptom usually being extreme weakness at birth.

Experiments have proved conclusively that goiter in new-born farm animals can be entirely prevented by supplying small amounts of iodine to pregnant animals during at least the last half of the pregnancy period.[31] The simplest method of furnishing iodine is to supply iodized stock salt during this period, instead of ordinary salt. Such salt should contain 0.007 per cent of iodine, and a process should be used to stabilize the iodine so as to prevent its loss into the air. Otherwise, on exposure much of the iodine will be volatilized.

If iodized salt is not readily available, it can be mixed on the farm by adding one-half ounce of finely-ground potassium iodide to 300 lbs. of salt. The mixture will contain a little more than 0.007 per cent iodine. Because of the small amount of potassium iodide used, it should be first mixed thoroughly with a few pounds of the salt, and this then be mixed with the rest of it.

In areas where iodine deficiency is most serious, it may possibly be wise to use iodized salt regularly in place of common salt for all stock, and not merely for pregnant animals. On the other hand, in districts where there is no deficiency of iodine, the use of iodized salt or other iodine supplements for farm animals does not seem advisable. Experiments have shown that an excess of iodine is definitely injurious to animals. Organic forms of iodine, such as kelp, are no more effective than iodized salt for preventing goiter. (977)

Certain drugs, especially thiouracil and thiourea, decrease the action of the thyroid gland and thus slow down metabolism. It is of interest, but not ordinarily of practical importance, that cabbage, turnips, and soybeans seem to

GOITER SOMETIMES CAUSES HEAVY LOSSES

A litter of pigs affected with goiter, or "hairlessness," caused by a lack of iodine in the ration of the sow. Some of the pigs are dead, while others are still alive, although very weak. After this sow had been given iodine in the form of potassium iodide during her next gestation period, she produced a litter of thrifty pigs. (From Hart, Wisconsin Station.)

have a similar effect on the thyroid gland. Thiouracil has sometimes been used to increase the rate of fattening of animals.

171. Iodine supplements in borderline areas.—It is rather surprising that there is but little goiter among livestock in many areas where it has been common among humans. Thus, there have been few cases of goiter in livestock in certain areas east of the Mississippi River where goiter is frequent in humans unless iodized salt is used.

Where the supply of iodine is rather low, but not deficient enough to cause noticeable goiter in new-born animals, the use of iodized salt may be beneficial. For example, using iodized salt instead of common salt for brood sows in a New York experiment reduced the number of pigs born weak or dead, although there had been very few cases of new-born pigs showing symptoms of goiter.[32]

Anyone who is in doubt as to whether or not it is advisable to use iodized salt in place of common salt for his stock under his local conditions can readily secure information from his state agricultural college or county agent.

A very limited amount of data indicates that navel-ill and weakness of foals may be lessened by feeding brood mares during pregnancy as much as 14 to 15 grains of potassium iodide a week, with their grain.[33] Further results are needed before final conclusions can be drawn concerning the merits of this treatment.

In areas where there is no definite deficiency of iodine for livestock, there has generally been no benefit from adding iodine to a normal ration. Several experiments have been conducted to study this question, including trials with dairy cows, dairy calves, pigs, lambs, and chickens.[34] Even in the trials where an iodine supplement has apparently been beneficial, the advantage has usually been slight.

In spite of these results, extravagant advertising claims are sometimes made for various iodine supplements. For example, statements have been made that such products will build up resistance to various diseases, will prevent sterility and other breeding troubles, will eradicate or prevent brucellosis (Bang's disease), will cause a great increase in product, or will markedly increase the efficiency with which feed is utilized.

172. Iron and copper.—An adequate supply of iron is necessary for animals, because the oxygen is transported in the blood by the hemoglobin, which is an iron-containing compound. Iron also has other necessary functions in the body. In spite of the importance of iron, the bodies of animals contain only a very small amount. Indeed, there is only 0.01 to 0.03 per cent of iron in the bodies of farm animals.

For hemoglobin formation there must be small traces of copper in the food, as well as an ample supply of iron, although hemoglobin contains no copper. Traces of copper are therefore necessary for animals, although this mineral is a violent poison when any considerable amount is taken into the body.

The amount of copper required by animals is very small, being only about one-tenth the requirement of iron, or even less. Where the need for copper is not increased by an excess of molybdenum or some other condition, a content of only 0.6 part of copper per million in the dry matter of forage is all that animals need. (173)

If the food of animals is too low in iron, or in copper or cobalt, nutritional anemia will result. In this disease there is a serious lack of hemoglobin in the blood. Such anemia is very different from pernicious anemia in man and from anemia caused by great loss of blood, as from a wound. At least in the case of some animals, anemias may also be caused by a deficiency of certain vitamins.

In all but very few areas of the world, the usual rations of farm animals supply an abundance of iron and copper, except perhaps during the suckling period, as is explained later in this chapter. With this exception, there is generally no need of adding copper or iron supplements to livestock rations.

In a few districts the soil is so lack-

ing in copper that serious disease is produced in livestock. Copper deficiency in cattle or sheep causes slow growth, failure to fatten, and severe anemia in extreme cases. In young cattle, a rickets-like condition may result and the bones may become fragile. Cows in a copper-depleted condition may fail to conceive or may have difficulty in calving, and the calves may be born rachitic. In copper deficiency, the hair of the cattle becomes bleached in color, and wool loses its natural crimp, but instead is straight and "steely." Where there is a deficiency of copper, the lack can readily be corrected by the use of such a mineral mixture as the "salt sick" mineral mixture widely used in Florida. (173)

A deficiency of copper is believed to be the cause of the trouble of sheep in West and South Australia called "stringy" or "steely" wool, of the disease of sheep in West Australia called "enzootic ataxia," and of "falling disease" or "sudden death" of dairy cattle in West Australia. "Coast disease" of cattle and sheep in Australia and other areas seems to be due to a deficiency of both copper and cobalt.

Some scientists doubt that a deficiency of iron ever occurs under natural conditions in livestock past the suckling age. However, on mineral-deficient soil at the Florida Range Experiment Station, when iron has been omitted from the mineral mixture for beef cattle, the results have not been so good as with an iron supplement.[35]

Using an iron or copper supplement when it is not needed may be injurious. An excess of iron tends to interfere with the absorption of phosphorus, through the formation of insoluble iron phosphates. Animals may be poisoned by the continued use of a mineral or salt mixture containing a far greater amount of copper than the mere trace needed by animals.

Sometimes medicated stock salt or mineral mixtures containing appreciable percentages of copper sulfate are sold as preventives of stomach worms or other internal parasites. It was found in Texas studies that heavy losses of sheep on certain ranches were due to the continued use of such medicated salt mixtures.[36]

With the exception of milk, nearly all common feeds have sufficient iron to meet the need of farm animals, even though the iron content is usually less than 0.01 per cent. Leafy forages, legume seeds, wheat bran, meat and fish by-products, and most oil meals are higher than the grains in iron, but the grains generally have enough. There is but little information concerning the actual availability of the iron in various feeds to farm animals, as nearly all such studies have been chemical tests or trials with small laboratory animals.

173. Correcting copper and other deficiencies.—The largest area in this country where copper deficiency occurs is in Florida. For many years it had been known there that cattle would not thrive on certain areas of poor, sandy land. They lost their appetites, they became emaciated and weak, and their blood was very low in hemoglobin. Young cattle were most affected and were often badly stunted. Many of the animals died from the disease, which is called "salt sick." Goats and sheep were also affected in certain of the areas.

It was finally found that these conditions were due to a serious lack in the forage of one or more of the trace minerals, including copper.[37] In certain areas, the chief deficiency is of cobalt, which is discussed later. Often the lack of trace minerals is associated with a deficiency of phosphorus or calcium, or of both of these minerals.

Recovery follows rapidly when the animals are allowed to take as much as they wish of a "salt sick" mineral mixture, such as the following: 100 lbs. common salt, 25 lbs. red oxide of iron, 1 lb. pulverized copper sulfate, and 1 ounce cobalt sulfate or cobalt chloride. One-half ounce cobalt carbonate may be used instead of the sulfate or chloride, as it is twice as high in cobalt. The mixture must be mixed very thoroughly, so no animal will get too much copper sulfate or cobalt, as they are poisonous if consumed in more than traces. In the areas

where the forage is also deficient in phosphorus or calcium, it is necessary to include these minerals also in the mixture.

In certain areas nutritional diseases occur that are prevented and cured by a copper supplement, even though the forage has a normal amount of copper. However, the assimilation and utilization of copper is prevented by an excess of another mineral or by some unknown cause.[38]

Investigations in England of the disease called "teartness" first revealed the cause of this trouble which occurred in ruminants, especially in calves and cows in milk. Animals suffering from this disease have serious diarrhea and run down in condition. It was found that although the pasture forage had a normal amount of copper, the animals were suffering from a copper deficiency, caused by a high content of molybdenum. The trouble could be entirely corrected by supplying a copper supplement. (Molybdenum is a mineral that is required in mere traces by plants.)

Other areas have since been found where this trouble, caused by excess molybdenum, occurs. Among these are a considerable district in southern Florida on organic soil, areas in southern California, and one in Manitoba, Canada.[39] Cattle are most frequently affected, especially young animals. Sometimes sheep are injured, and also even horses, swine, and chickens.

The amount of copper needed in a mineral mixture to prevent the disease will depend on the molybdenum content of the forage. Advice should therefore be secured from the local agricultural college or experiment station as to the proper mineral mixture to use in any particular area. In the Everglades district of Florida, the following mixture is recommended: Steamed bone meal 50.0 lbs., common salt 44.7 lbs., pulverized copper sulfate 2.5 lbs., copper oxide 0.8 to 1.2 lbs., depending on the copper content, and cobalt carbonate 1.0 ounce or cobalt sulfate or chloride 2.0 ounces. (Copper oxide is used to furnish part of the copper, as it is less soluble and less toxic than copper sulfate. Two pounds of aluminum sulfate is sometimes added to the mixture but is not considered necessary.)

Another copper deficiency disease that occurs with a normal amount of copper in the forage is "swayback" of new-born and young lambs, which occurs in several areas in Great Britain. The lambs suffer from incoordination or paralysis of the legs and often die. The trouble can usually be prevented by feeding a copper supplement to the ewes during pregnancy. This can be done by mixing 0.3 lb. of copper sulfate with each 100 lbs. of salt. The forage in these areas is generally normal in copper content, but it is apt to have an unusually high content of lead and zinc, which apparently interferes with the utilization of the copper in the feed. "Copper pine" of calves also occurs in some areas of Scotland with a normal content of copper in the forage, and no excess of molybdenum.[40]

174. Anemia of suckling animals.—Milk is exceedingly low in iron and also in copper, and it is not possible by any method of feeding the mother to increase the amounts of these minerals in her milk. To offset this lack, young mammals are born with a store of the minerals in their bodies which normally suffices until they begin to eat other food that supplies plenty of these minerals. If they are kept on milk alone for an unusual length of time, disaster will follow because of these and other lacks.

When young farm animals are raised under normal conditions and are allowed to eat other feed as soon as they will take it, there is generally no trouble whatsoever from anemia (the lack of hemoglobin), except in the case of suckling pigs which are not on pasture but are confined away from the soil. Anemia may readily be prevented in such suckling pigs by one of the methods described in Chapter XXXIV.

175. Cobalt.—In 1935 it was first reported that certain serious diseases of grazing stock in Australia were definitely caused by a deficiency of cobalt in the

feed.[41] Since then, in widely-scattered areas of the world, it has been proved that lack of cobalt or of both cobalt and copper is the cause of hitherto baffling diseases of ruminants.

In North America, it has been determined that a lack of cobalt has produced serious troubles in certain areas of Florida, Maine, New Hampshire, Michigan, New York, Wisconsin, and Western Canada.[42] However, cobalt-deficiency is distinctly a local problem, and in most of our country there is apparently no lack of cobalt in livestock feeding.

after cobalt is supplied. It is sometimes difficult to distinguish the symptoms of cobalt deficiency from those caused by a lack of phosphorus. However, if the appetite is not improved decidedly after 2 weeks of cobalt feeding, the trouble is not due to cobalt deficiency. In this way, one can readily find whether a cobalt deficiency is actually the cause of the malnutrition in his stock.

Cobalt is required by the bacteria which are so important in the digestion of feed and the synthesis of B-complex vitamins by ruminants. It is believed that the chief cause of cobalt-deficiency trou-

THE PIG ON THE LEFT HAS SEVERE ANEMIA

These pigs are litter mates. The one on the left was raised by its mother in a hog house and a small paved exercise lot, without access to the soil. It has severe anemia, due to the lack of iron and copper in milk. The thrifty pig on the right was transferred soon after birth to a sow whose udder was swabbed with a solution of ordinary iron sulfate. (From J. P. Willman, Cornell University.)

In cobalt-deficient areas, the trouble occurs both with stock on pasture and with animals fed winter rations. Young animals are more apt to be affected than mature ones.

Cattle or sheep suffering from cobalt deficiency lose their appetites, become unthrifty and emaciated, and may have a depraved appetite, especially a desire to eat hair or gnaw wood or bark. A serious anemia may also be produced. Young animals fail to make proper growth, and in severe cases animals may "pine away" and die. On some farms affected by the trouble, a considerable proportion of the lambs have been lost because of this deficiency.

Cobalt-deficient animals usually show marked improvement in appetite and other conditions within 3 to 7 days

bles in ruminants is a lack of vitamin B_{12}, produced by a greatly lessened formation of this vitamin in the rumen when there is a serious lack of cobalt in the food. Cobalt-deficiency in sheep has been cured by feeding or by hypodermic injection into the blood of sufficient amounts of vitamin B_{12}.[43]

These discoveries explain why non-ruminants need less cobalt than do ruminants. Horses, on the same pastures where cattle suffer from cobalt deficiency, are not affected. However, even non-ruminants, such as swine and poultry, need minute traces of cobalt, because vitamin B_{12}, which they require, contains cobalt. (220) In recent experiments adding cobalt to low-cobalt rations for growing pigs has increased the gains.

Only mere traces of cobalt are required by cattle and sheep, a content of 1 part of cobalt in 10 million parts of the ration, on the dry basis, providing an ample amount. The requirement for sheep seems to be slightly higher than for cattle. Sheep show definite symptoms of cobalt deficiency when pasture forage has less than about 0.7 part per 10 million, on the dry basis, while cattle may not suffer until the content is 0.4 part per 10 million parts. Before the cause of the disease was discovered, farmers had found that it could be cured by moving the affected animals from the "sick" area to a "healthy" pasture. Investigations showed later that the recovery on "healthy" areas was due to a higher cobalt content of the forage.

Legume forage generally has more cobalt than do the grasses, but yet may sometimes be deficient. Timothy seems to be often especially low in cobalt. Recent studies have shown that heavy fertilization of soil rather low in cobalt with ordinary complete fertilizer may reduce the cobalt content of forage, because of the heavy crop yields.[44]

In cobalt-deficient areas trouble from the lack of cobalt can be prevented by mixing 1.0 ounce of cobalt sulfate or cobalt chloride, or else 0.5 ounce of cobalt carbonate, in each 100 lbs. of salt. In order to mix this very small amount of cobalt salt thoroughly with the common salt, it is best to dissolve it in a little water, spray it over the salt with a small fly sprayer, and then mix the salt well. Thorough mixing is essential, so that no animal will get a large excess of cobalt, which would be injurious. In cobalt-deficient regions, the needed trace of cobalt is rather generally added by the manufacturer to commercial formula feeds.

Although an animal can be poisoned by a considerable amount of a cobalt salt, no injury is produced by a ration that contains one hundred times the amount actually needed.[45]

Where there are deficiencies of copper or iron in addition to cobalt, such a mixture as the "salt sick" mineral mixture used in Florida should be fed. (173) In an area where the salt content of the pasture forage is so high that the animals do not eat much salt, as in some areas of Scotland, 3 lbs. of cobalt sulfate per acre can be mixed with superphosphate and applied to the pasture.

For animals already seriously affected by cobalt deficiency, it may be necessary to administer cobalt as a drench. For mature cattle a suitable treatment is 1 tablespoonful per day of a solution of 1 ounce of cobalt sulfate in 1 gallon of water, for a week or two, after which the cobalt can be supplied in the salt. For very young calves 2 teaspoonfuls of this solution per day can be added to the milk for the first couple of weeks.

EFFECTS OF COBALT DEFICIENCY

Left, yearling heifer suffering from severe cobalt deficiency on cobalt-deficient pasture. Right, the same heifer 2 months before freshening and 7 months after she had been supplied with a "salt-sick" mineral mixture containing cobalt, on the same pasture. The heifer showed marked recovery within 2 months after cobalt was supplied. (From Becker, Florida Station.)

Except in areas where a cobalt deficiency is known to exist, or where symptoms strongly indicate such a deficiency, there is no advantage in adding cobalt to salt or to a mineral mixture. A normal appetite for feed shows that animals are getting sufficient cobalt in their usual rations.

A lack of cobalt or a combined deficiency of cobalt and of copper and perhaps iron has been found to be the cause of "salt sickness" in cattle and sheep in Florida. Cobalt deficiency is the cause of "bush sickness" and similar diseases of sheep and cattle in certain areas of New Zealand and Western Australia. The "pining disease" of sheep in some districts of Scotland and England is usually due to cobalt deficiency, while the "coast disease," which affects cattle, sheep, and goats in South Australia and certain other regions, is apparently caused by a lack of both cobalt and copper.

176. Sulfur.—Sulfur is necessary for animals, because it is an essential part of most proteins and also of certain vitamins and other compounds needed in the vital processes of the body. In proteins, sulfur occurs in methionine, one of the essential amino acids, and also in cystine, which can partially replace methionine in function.

Fortunately, animals need but a very small amount of sulfur in their food, and plenty is apparently furnished by nearly all well-balanced rations. Sheep require more sulfur than do other farm animals, because wool is high in cystine, having about 4 per cent. However, in a Canadian experiment with ewes, there was no benefit from adding sulfur to a low-sulfur ration that had only 0.08 per cent sulfur.[46] In an Oregon trial with dairy cows, there was no advantage in adding sulfur to a low-sulfur ration which had 0.1 per cent sulfur.[47]

Most rations supply more than these amounts of sulfur.[48] However, in a few areas, as in certain districts of the northwestern coast states, the soil is so low in sulfur that the yield and also the sulfur content of legume forage crops are much reduced, unless a sulfur fertilizer is applied. In an Oregon experiment, lambs fed such low-sulfur alfalfa hay gained considerably less than did others fed alfalfa from a sulfur-fertilized plot.[49]

It was formerly believed that animals had little, if any, ability to use sulfates or free elemental sulfur for making the sulfur-containing amino acids. Recent experiments have proved, however, that ruminants fed a low-sulfur ration can use sulfates and even free sulfur for this purpose to a limited extent, though such sulfur may be less effective than that supplied by methionine.[50] Such synthesis of simple forms of sulfur into the sulfur-containing amino acids probably comes about through the bacterial action in the rumen. However, even chicks can apparently use some sulfate sulfur for protein formation when added to a low-sulfur ration.[51]

It has been shown in Chapter V that the protein in certain common feeds, especially some legume seeds, is low in methionine and cystine, and therefore is inefficient for non-ruminants unless this lack is corrected. (**122**)

Adding finely powdered sulfur to a poultry mash tends to prevent coccidiosis, but such addition greatly increases the vitamin D requirement. It is therefore detrimental unless the birds have an abundant supply of this vitamin. Claims have been made that the feeding of sulfur or sulfurized salt to cattle would repel lice or flies, but there was no such effect in Texas and Kansas tests.[52]

177. Potassium.—Potassium is essential for animals, and the bodies of animals contain more potassium than they do of either sodium or chlorine. However, the usual feeds supply ample amounts of potassium, and there is no need of adding potassium supplements to livestock rations.

Very heavy fertilization with potassium may greatly increase the potassium content of forage crops and reduce the calcium so much that a calcium supplement is needed by dairy cows or other stock.[53]

It has been a disputed point as to whether or not the presence in a ration of a considerable amount of potassium

will cause an increased excretion of sodium, and therefore a greater need for common salt.[54] Though this often does not seem to be the result, nevertheless herbivora, living largely on forage plants, which are generally high in potassium, require more salt than swine and poultry, which consume rations rather lower in this mineral.

178. Magnesium.—Magnesium is present in very small amounts in the bodies of animals, forming only from 0.02 to 0.05 per cent of the bodies of farm animals. Nevertheless, it is necessary for life. If experimental animals are fed rations from which the magnesium has been removed as completely as possible, they will show increasing irritability after a few days and a little later die in convulsions.

Most normal feeds contain the small amounts of magnesium that are necessary for animals. Therefore, there is generally no lack of it in any ordinary ration fed livestock.

In experiments to determine magnesium requirements, only 0.06 per cent has been needed by dairy calves, 0.04 per cent by chicks, and 0.05 per cent by ducks.[55] Most feeds have much more magnesium than this. For example, alfalfa hay has 0.29 per cent and corn grain 0.10 per cent. (Appendix Table IV.)

When whole milk is fed to calves as the only food for an unnaturally long period, it is apparently necessary to add a magnesium supplement, as well as iron and copper.

It was formerly believed that magnesium had a decidedly antagonistic action toward calcium in the body, and that an excess of magnesium would cause a large loss of calcium, thus producing injury. More recent experiments have shown, however, that unless the excess of magnesium is very large, no bad results will be produced, provided that the ration has an ample supply of calcium and phosphorus. As has been stated earlier in this chapter, dolomitic or magnesian limestone is fairly satisfactory as a mineral supplement, except for poultry. (157)

179. Grass tetany; wheat or oat pasture poisoning.—A serious disease, called grass tetany or grass staggers, in which the blood has a very low content of magnesium and often also of calcium, has been reported from many parts of the world.[56] It occurs chiefly in milking cows, often shortly after calving, and in lactating ewes, but has also been reported in dry cows, steers, and calves. It frequently appears soon after the animals are turned to pasture in the spring. The usual symptoms are nervousness, lack of appetite, rapid breathing and pulse rate, and finally convulsions and coma, often ending in death. The poisoning that sometimes occurs on young wheat or oat pasture seems to be similar to or the same as grass tetany.

The exact cause of the disease has not been determined. Sometimes the forage is low in magnesium, but in other cases the content is normal. The most commonly used treatment is the hypodermic injection of a solution of calcium gluconate, with or without the addition of glucose, magnesium, or phosphorus.[57] If the animal is not treated before it loses consciousness, there is little chance of recovery. In some cases the feeding of a magnesium supplement, or providing dry feed in addition to pasture, has apparently aided in preventing the trouble.

180. Manganese.—Manganese is essential for animals and also for plants, but only mere traces are needed. All ordinary feeds have small amounts of manganese, and most rations apparently furnish plenty for all classes of stock except poultry, which have unusually high requirements for it.

Claims have been made that manganese or other trace mineral supplements will prevent or cure brucellosis (Bang's disease) in cattle. However, in Wisconsin, Ohio, and Missouri experiments such supplements have had no such effect.[58]

The special needs of manganese by poultry for the prevention of perosis, or "slipped tendon," and for hatchability of eggs are discussed in Chapter XXXVI. The small amount of manganese needed, even by poultry, is shown by the fact

that the addition of only one-quarter pound of manganese sulfate per ton of poultry mash provides insurance against a deficiency of the mineral.

Symptoms of manganese deficiency have been produced in rats and rabbits by feeding them highly-purified experimental rations containing practically no manganese. In rats a deficiency of manganese lessens growth, produces poor bones, and impairs reproduction and lactation. In rabbits it causes weak bones and crooked legs.

The manganese requirements of swine have been investigated by using purified rations exceedingly low in the mineral, or rations having an unusually low manganese content. From Wisconsin trials it was concluded that swine need 25 to 30 parts of manganese per million parts of feed for optimum growth and best reproduction.[59] In a Florida experiment a ration having only 3 parts per million of manganese depressed early growth, and sows raised on this ration produced weaker pigs than did those receiving more manganese.[60] However, in Arkansas and Indiana studies pigs grew normally on rations extremely low in manganese, having only 0.5 to 1.5 parts per million.[61]

A considerable excess of phosphorus in a ration interferes with the utilization of manganese, because of the formation of compounds in which the manganese is unavailable. Apparently for this reason, in Pennsylvania experiments pigs developed stiffness and crookedness of the legs and enlarged hocks on rations containing considerable low-grade tankage, which was very high in bone.[62] Adding a manganese supplement to the ration prevented the trouble, but did not cure it after it had developed.

In Indiana studies with dairy calves, the growth rate was a trifle less and sexual maturity was delayed on a ration having only 6 to 8 parts of manganese per million, in comparison with higher levels.[63]

Most hays have 20 or more parts of manganese per million. The grains are lower, as a rule, corn being especially low. Wheat bran, wheat middlings, and rice bran are particularly high in manganese.

181. Zinc.—Very little information is available concerning zinc in animal nutrition. Experiments with rats fed highly purified diets, freed as thoroughly as possible from zinc, have shown that traces of it are necessary for good growth and also for normal hair development.[64]

It has just been found in experiments that adding a zinc supplement to a ration helps prevent and cure parakeratosis in swine, a skin disease that somewhat resembles mange but is apparently of nutritional origin.[65] A ration that has an excessive amount of calcium supplement seems to increase the trouble.

In swine herds where parakeratosis has been prevalent, it is recommended that 0.5 lb. of zinc carbonate or 1.0 lb. of zinc sulfate should be added per ton of the feed mixture. This should be discontinued about 2 weeks before the swine are sold for slaughter.

With this exception, there is no need of adding a zinc supplement to any ordinary ration, so far as we know. Claims have been made that a zinc supplement will increase the length of life of farm animals, but the author has seen no scientific evidence to this effect.

On account of the wide use of galvanized (zinc-coated) containers for liquids, studies have been conducted to find whether or not sour foods would dissolve sufficient zinc to be poisonous to animals. In Oklahoma tests buttermilk stored in galvanized tanks for some time was not poisonous to rats.[66] Probably most cases of poisoning attributed to zinc have been due to lead, which is present in most zinc coatings.

182. Charcoal; coal.—Wood charcoal or coal is sometimes included in mineral mixtures or added to concentrate mixtures, especially for swine or poultry. Charcoal consists chiefly of carbon in elemental form and supplies but little mineral matter. Its use is sometimes advocated as a corrective of diarrhea and an absorbent or adsorbent of gases and of detrimental decomposition products produced in the intestines.

However, several experiments with growing and fattening pigs have conclusively proved that adding charcoal or either hard or soft coal to an ordinary ration is not beneficial or economical.[67] In these trials more feed has usually been required per 100 lbs. gain on rations with added charcoal or coal than without such addition.

California experiments with chicks show that charcoal tends to absorb vitamins and hold them so that they are not available.[68] Therefore adding charcoal to a ration may produce a vitamin deficiency, unless the ration contains a greater supply of vitamins than the minimum amount ordinarily needed.

In New York experiments with chicks and with laying hens the addition of charcoal to the ration did not have any beneficial effect on growth, egg production, feed utilization, or mortality.[69] In cases of severe diarrhea the condition of the droppings was not influenced by charcoal, though there was some improvement in mild diarrhea.

183. Acid-base balance.—In the tissues, a proper balance must be maintained between the alkaline, or basic, compounds and the acidic compounds in the blood and other body fluids. Some minerals, such as phosphorus, chlorine, and sulfur, are acid in reaction, while others, such as calcium, sodium, potassium, and magnesium, are alkaline. The proportion of bases and of acid constituents in the food often varies widely. It is therefore fortunate that the body has much ability to maintain the neutrality of the blood in spite of considerable differences in the intake of alkalies and acids in the food.

Farm animals, especially ruminants, have great ability to produce ammonia in the body tissues to neutralize any ordinary excess of acid. Therefore, any amount of acid that may be present in an ordinary ration is not injurious, if the ration furnishes sufficient amounts of calcium and other essential minerals.

Organic acids, such as the lactic acid and acetic acid in silage, do not tend to produce an acid reaction in the body. If they are completely oxidized, they yield only carbon dioxide and water. For this reason, experiments have abundantly proved that the continued feeding of liberal amounts of corn silage to dairy cows for several years has no injurious effect whatsoever.[70] Also, cows, calves, and swine have been fed without harm greater amounts of dilute mineral or organic acids than would be contained in any normal ration.[71]

Only when silage preserved with phosphoric acid or other mineral acids is fed, is there usually any need of giving attention to the acid-base balance of the ration. In feeding such silage, ground limestone or a mixture of limestone and sodium bicarbonate should be added. (432)

184. Does apparent craving for minerals indicate deficiency?—When farm animals gnaw bones, wood, or other objects, or eat dirt, it often indicates a deficiency of phosphorus or some other mineral. (155) However, sometimes animals show such a tendency when there is no deficiency whatsoever. For example, horses often gnaw wooden mangers when they are in excellent health and are amply supplied with all nutritive essentials. When livestock display such tendencies, one should investigate the possibility of a mineral deficiency in their rations, and then correct any such lack.

That such a tendency does not always indicate a lack of a mineral is well shown by an interesting case at the National Institute for Research in Dairying in England.[72] Pigs eagerly licked and gnawed copper rings at the base of steel posts in the pens of the swine barn. A test was therefore conducted in which plates of various metals were placed in the pens. The pigs showed a tendency to lick only the plates of copper or copper alloy. It might have been supposed that this indicated a lack of copper in their feed. However, careful tests showed that there was no benefit from adding a copper salt to the ration.

185. Trace minerals; trace mineralized salt.—It has been shown previously in this chapter that in certain areas, and only in certain areas, deficiencies occur of one or more of the trace minerals—

iodine, copper, iron, cobalt, and manganese. The dramatic curing of serious livestock trouble by the use of a very small amount of a trace mineral has caused many stockmen to wonder whether they should not regularly supply their animals with a mixture of trace minerals as insurance against any possible deficiency.

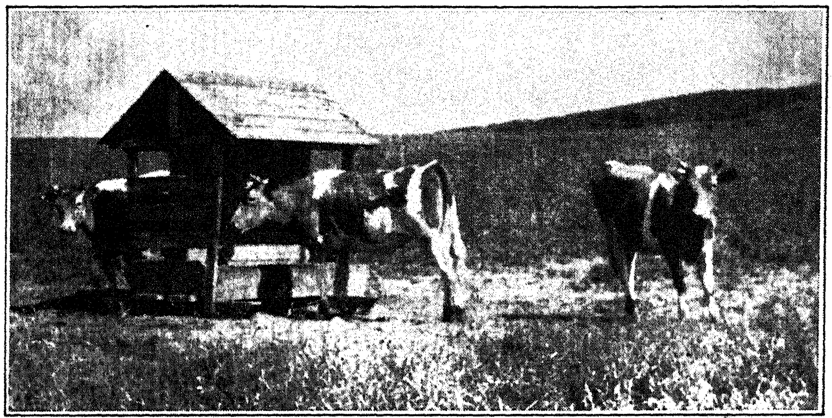
Some of the large salt companies are marketing trace mineralized salt to which the various trace minerals have been added. Trace minerals are also now included in many commercial mineral mixtures and formula mixed feeds.

It should be borne in mind that over much of our country there are no known deficiencies for the larger farm animals of any of the trace minerals. Where there is no deficiency of a trace mineral, money spent for trace mineral supplementation is wasted. If a stockman is in doubt as to whether or not it will be profitable for him to purchase a trace mineral supplement for his animals, the wise plan is to secure advice from his agricultural college, experiment station, or county agent.

In the chapters dealing with the various classes of stock, there are summarized the experiments in which the addition of trace minerals to ordinary rations has been tested. In Chapter XXXVI very recent experiments are summarized which indicate that for optimum growth chicks require an unidentified trace mineral or a combination of minerals, in addition to the previously known mineral needs.

186. Using simple mineral mixtures.—When a ration is fed that is deficient in calcium or in phosphorus, this lack should be corrected by the use of a suitable mineral supplement, as has been shown previously. When a mixture of ground concentrates is being fed, the proper amount of the mineral supplement may be mixed with the concentrates. In other cases, the mineral supplement is best mixed with salt to make it more palatable, and the mixture then placed in a suitable box or trough, where the stock can have access to it. The instinct of farm animals guides them to consume enough of the mineral mixture to correct the deficiency in the ration. In a humid region the mineral feeder should preferably be covered, to protect the contents from rain.

If the only deficiency is of calcium, such a mixture as 2 parts by weight of ground limestone or some other calcium supplement and 1 part of common salt is satisfactory. A mixture like this is very much cheaper than one that supplies phosphorus in addition. If phosphorus is deficient and there is plenty of calcium



A COVERED FEEDER PROTECTS MINERALS FROM RAIN

A convenient covered feeder for supplying cattle on pasture with salt and a mineral mixture. (From New York State College of Agriculture, Cornell University.)

in the ration, such a mixture as 2 parts or more by weight of bone meal or some other safe phosphorus supplement and 1 part common salt is excellent. It should be remembered that bone meal supplies both phosphorus and calcium, and contains twice as much calcium as it does of phosphorus.

If there is a decided lack of calcium in the ration and also a possible deficiency of phosphorus, then a combination of a calcium supplement with a phosphorus supplement like bone meal may be desirable. It has been emphasized in this chapter that for cattle, sheep, and horses, there is only rarely a deficiency of calcium, except in the case of fattening cattle or sheep fed non-legume roughage. Where there is probably no lack of calcium, it is unwise to use a mineral mixture that is high in calcium and relatively low in phosphorus.

Such a mixture as 4 parts by weight of steamed bone meal, 4 parts of ground limestone, and 2 parts of salt is often used for all classes of stock, but this supplies 4 times as much calcium as phosphorus. Unless there is a decided lack of calcium in the ration, a better mixture for cattle, sheep, and horses is a mixture of bone meal and salt, or such a combination as 60 parts by weight of steamed bone meal, 20 parts of ground limestone, and 20 parts of salt.

In using one of these mixtures, it is wise to supply common salt separately in addition, so that the animals will not have to consume more of the mineral mixture than they need in order to get sufficient salt. However, in an area where the forage, water, or soil has considerable salt, animals consume much less salt than usual. If salt is provided separately, they may then not take the needed amount of phosphorus or calcium supplement.

If no salt is supplied separately, a mineral mixture for cattle should contain one-half salt and a mixture for swine at least one-third salt. A suitable mixture for cattle, when no additional salt is provided, is 2 to 3 parts by weight of bone meal, 1 part ground limestone, and 3 parts common salt. A good mixture for swine is made up of equal parts by weight of these three supplements.

In areas where there is trouble from goiter in livestock, one-half ounce of potassium iodide should be included in each 300 lbs. of mineral mixture for pregnant animals, unless iodized salt is fed separately. In the localities where there is a deficiency of copper or cobalt, these minerals should be supplied, as previously advised.

187. Commercial mineral mixtures.—Many commercial minerals for the various kinds of stock are on the market. Some of these are composed entirely of the satisfactory phosphorus and calcium supplements, common salt, and often trace minerals. Others are more complex, containing in addition such substances as Epsom salts, Glauber's salts, sulfur, sodium carbonate, silicates, and charcoal.

In the experiments in which such complex mineral mixtures have been compared with more simple mixtures, the complex mixtures have generally been no better.

Before purchasing a commercial mineral mixture, one should note carefully the guaranteed content of various minerals, especially of phosphorus and of calcium. If his stock need chiefly a phosphorus supplement, it is uneconomical to buy a mineral mixture that has several times as much calcium as it has of phosphorus.

Because limestone and other calcium supplements are so much cheaper than bone meal or other safe phosphorus supplements, commercial mineral mixtures are apt to be relatively low in phosphorus. Some have 4 to 6 times as much calcium as phosphorus, and yet are sold at a high price. If the chief need of the animals is for additional phosphorus, the purchase of such a mineral mixture is not wise.

QUESTIONS

1. What are some of the vital functions of minerals?
2. Discuss the importance and use of common salt in stock feeding.
3. What use is made in range areas of the

ability of cattle and sheep to consume large amounts of salt without injury?
4. Why are calcium and phosphorus of especial importance in stock feeding? Why is there now more often a lack of these minerals than formerly?
5. How do the bones serve as a storehouse of calcium and phosphorus?
6. State the relative calcium content of the following: (a) Legume forage; (b) non-legume forage; (c) cereal grains and other seeds and their by-products; (d) milk; (e) meat scrap, tankage, and fish meal.
7. State the relative phosphorus content of each of the above groups of feeds.
8. Why is a calcium supplement advisable for swine and poultry, while it is not generally needed for cattle, sheep, or horses?
9. When may a lack of phosphorus occur in feeding the following: (a) Dairy cows; (b) beef cattle and sheep; (c) swine and poultry?
10. By what kind of stock is phytin phosphorus not well utilized?
11. For what kinds of stock is the calcium-phosphorus ratio important?
12. What is the cause of rickets? Describe its effects.
13. What are the effects on mature animals of a lack of calcium or phosphorus?
14. How do the symptoms of phosphorus deficiency and of calcium deficiency in dairy cows differ?
15. Name 5 satisfactory calcium supplements.
16. Name 4 safe phosphorus supplements.
17. Discuss the effects of fluorine on livestock.
18. What is the importance of iodine for farm animals? Would you feed an iodine supplement to stock in a non-goitrous area?
19. Explain why iron and copper are needed by animals. Which of these minerals is definitely deficient in certain areas?
20. What are the symptoms of copper deficiency?
21. Why is a copper supplement needed in certain areas where the forages have a normal copper content?
22. Why does anemia occur in suckling pigs?
23. What are the symptoms of cobalt deficiency? Has any definite deficiency of cobalt been found in your district?
24. From what sources do animals get nearly all of the sulfur they need?
25. How can ruminants use sulfates or free sulfur?
26. Is there a need for adding the following to the rations of any class of livestock: (a) Potassium; (b) magnesium; (c) manganese; (d) zinc; (e) charcoal?
27. What is grass tetany?
28. When is it necessary to give attention to the acid-base balance of feeds?
29. Does an apparent craving for minerals always indicate a deficiency?
30. Is there a need of trace minerals in your area? Which are apparently lacking?
31. State a satisfactory mineral mixture for use under each of the following conditions: (a) When only calcium is lacking; (b) when both calcium and phosphorus are lacking; (c) for cattle fed no additional salt, when both phosphorus and calcium are lacking.
32. Discuss the use of complex mineral mixtures.

CHAPTER VII

VITAMINS IN LIVESTOCK FEEDING

I. Importance of Vitamins

188. Modern rations based on vitamin discoveries.—Our present-day efficient rations for livestock, especially for poultry and swine, have largely been made possible because of the rapid succession of discoveries concerning vitamins. These discoveries have not only greatly increased the efficiency of animal production, but also have made possible the prevention of serious nutritional diseases.

For example, before the functions of vitamins were known, pigs that were born in the fall in the northern states often failed to thrive and many became paralyzed or died from pneumonia or other diseases. This fall-pig problem has been solved through the use of improved rations that provide an ample supply of the essential vitamins. Similarly, before the necessity of vitamins in poultry feeding was understood, it was difficult to grow thrifty chicks during the seasons of the year when they could not get out in the sunshine and secure green forage. Now they can be raised efficiently at any season of the year.

In the southern states cattle fed heavily on cottonseed meal often died from what was thought to be "cottonseed meal poisoning." It was discovered that the trouble was due mainly to a vitamin deficiency. As a result, it is now possible to feed dairy cows for long periods on cottonseed meal as the only concentrate without any injurious results whatsoever.

The discoveries concerning the occurrence and functions of vitamins have nearly all been made since 1911. Previous to that time even the existence of vitamins as definite food essentials was unknown. It was then generally believed that the only requirements to make a satisfactory diet for humans or a complete ration for farm animals were adequate supplies of proteins, carbohydrates, fats, and minerals.

Certain investigators had previously reported that laboratory test animals, such as rats or mice, did not thrive on a highly-purified diet made up of the nutrients that were then known. Furthermore, they had found that when certain natural foods, like milk, were added to such a diet the animals would thrive. They therefore concluded that some other substances must be essential for animal life, in addition to the recognized classes of nutrients. It is rather surprising that these interesting observations attracted little attention at the time from other investigators.

In 1912 it was discovered that a mysterious substance (now known as thiamine) was able to prevent or cure the disease called beri-beri in experimental animals. This substance was called "vitamine." The general name of *vitamin* has since been used for the considerable number of mysterious organic substances, discovered later, which are essential for animals but which are needed in only exceedingly small amounts.

Shortly after the discovery of the first vitamin was announced, it was reported that scurvy in experimental guinea pigs could be cured by feeding small amounts of fresh green feeds that supplied the antiscorbutic factor, which we now call ascorbic acid or vitamin C. Then, in 1913 investigators in two different laboratories discovered a food essential in butterfat (now known as vitamin A), which was necessary for growth and even for life itself. Since that time hardly a year has passed without some discovery of major significance in this field.

In addition to the considerable number of vitamins which have been definitely isolated and investigated, experiments with poultry have shown that there are still other unidentified vitamins which are essential, at least for them. (222)

The various vitamins that have been identified are widely different in chemical structure. The vitamins are therefore not related chemically to each other, as as are the proteins, the fats, or the carbohydrates. The functions of the various vitamins are also entirely different. The vitamins are grouped together because each vitamin is organic in nature and because, at least for certain animals, it is a nutritive essential required only in an exceedingly small amount.

A *vitamin* may be defined as an organic nutritive essential which is required in only a very minute amount.

Certain vitamins are apparently needed by but a few species of animals. Others are probably required by all species, but there is no need for a supply in the feed. This is because an ample amount of the vitamin is synthesized, either in the body tissues or by bacteria within the digestive tract. Vitamin A is required by all animals and can be made in the body only from carotene contained in plants. Animals must therefore receive in their food a sufficient supply of vitamin A or of carotene.

Only the briefest summary can be presented here concerning the functions and the occurrence in various feeds of the different vitamins. The special vitamin requirements of each class of stock are discussed in the respective chapters of Part III. For further information concerning the chemistry and functions of the vitamins, the reader is referred to recent texts on biological chemistry and to the books dealing exclusively with this subject.[1]

EXPERIMENTS WITH RATS HAVE SOLVED MANY PROBLEMS

Much of our knowledge concerning proteins, vitamins, and minerals has been gained through experiments with small laboratory animals. Equipment for investigations with rats and other small animals in the Animal Nutrition Laboratory, Animal Husbandry Department, Cornell University. (From McCay and Maynard.)

189. Vitamin content of important feeds.—The information concerning the amounts of the different vitamins in various feeds is exceedingly limited, in comparison with the great numbers of analyses for the ordinary nutrients, and even for calcium and phosphorus. Fur-

thermore, the amounts of a particular vitamin in various lots of a certain kind of feed may vary widely, depending on the quality of the feed, the stage of growth, and in the case of hay or other dry forage, on how it has been cured.

The approximate amounts of carotene (vitamin A value) and of thiamine, riboflavin, niacin, pantothenic acid, and choline in some of the most important feeds are stated in Appendix Table V, so far as data are available. The information concerning the content of the other vitamins is very limited. So far as data are available, the approximate amounts of other vitamins in certain feeds are stated in Appendix Tables Va, Vb, Vc, and Vd.

One of the exceedingly important facts in livestock production is that all green forage crops are rich in most of the vitamins required by farm animals. The only exceptions seem to be vitamin D and vitamin B_{12}. In the case of animals on pasture and thus exposed to sunlight, vitamin D is supplied by the effect of the ultra-violet rays in sunlight. While the green forage plants thus far studied do not seem to have appreciable amounts of vitamin B_{12}, nevertheless poultry on good pasture do not apparently need any vitamin B_{12} supplement, although they have a definite requirement for the vitamin.

Silage and well-cured hay, especially alfalfa and other legume hay, are also good sources of most of the vitamins. Hay and other dry forage cured in the sun even supply considerable vitamin D. When farm animals are not on pasture, plenty of good hay and silage will ordinarily provide ample amounts of vitamins, except in the case of poultry, which need vitamin supplements, as emphasized in Chapter XXXVI.

Green forage crops not only supply most of the vitamins which have been discovered thus far, but they also furnish other unknown vitamins that are needed by livestock. This is shown by the fact that farm animals may suffer from nutritive deficiencies when never allowed on pasture or fed fresh green forage.

For example, it is shown in Chapter XXXIV that brood sows which are kept in dry lot are often unable to reproduce normally, even when fed an apparently well-balanced ration. When pasture or other green feed is supplied, the ration is made complete, and the sows can raise thrifty litters.

Alfalfa or other legume hay of good quality is the best substitute for pasture in furnishing unknown but necessary vitamins. However, even the best of hay is not a perfect substitute for green feed such as pasture. It is therefore important that good pasture be provided for livestock, and especially for breeding animals, during as much of the year as possible.

190. Antivitamins, or antimetabolites.—In certain cases a food may contain a substance that prevents the action of a vitamin or even destroys it. Such a substance is called an *antivitamin,* or antimetabolite, for the vitamin. An example of this action is a paralysis of foxes raised for fur, which is caused by an antivitamin in certain raw fish that destroys the vitamin thiamine. Bracken fern poisoning of cattle also seems to be caused by an antivitamin of thiamine.

II. Vitamin A and Carotene

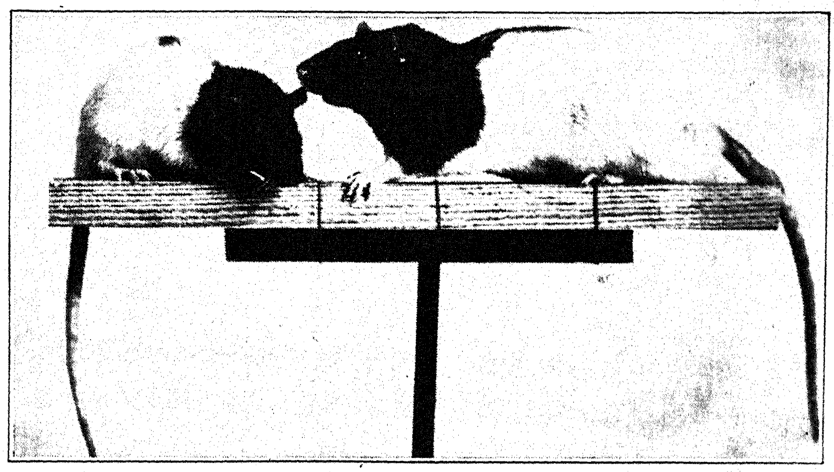
191. Importance of vitamin A.—In livestock feeding, as well as in human nutrition, vitamin A ranks first in importance among the vitamins. It is required by all animals, including poultry, and it is often deficient in practical rations. Unless care is taken to include in the rations fed farm animals a sufficient amount of feeds rich in vitamin A value, the results will be unsatisfactory and disaster may follow.

Vitamin A is essential even for the maintenance of mature animals. For growth, reproduction, and milk production, greater amounts are needed than for mere maintenance.

Vitamin A does not occur as such in feeds of plant origin. However, as is shown later, green-leaved plants and certain other feeds of plant origin contain substances grouped under the term *carotene,* which can be converted into vitamin A within the bodies of animals.

The *vitamin A value* of a feed or a ration means the total vitamin A potency, no matter whether it is supplied by vitamin A or by carotene.

The vitamin A requirements of each class of livestock are considered in detail in the respective chapters of Part III. The amounts of carotene or vitamin A advised for the various farm animals are stated in the Morrison feeding standards. (Appendix Table III.) For all classes of stock except poultry, the requirements are stated in terms of carotene, since these animals usually get their supply of vitamin A in this form. For poultry, the requirements are stated in U.S.P. (United States Pharmacopoeia) units of vitamin A value, which take into consideration both vitamin A and carotene. This is done because in poultry feeding vitamin A value may be supplied both in the form of carotene, as in alfalfa meal or green feeds, and in the form of actual vitamin A, as in fish oils.



VITAMIN A WAS DISCOVERED IN EXPERIMENTS WITH RATS

The thrifty rat on the right received plenty of vitamin A in the form of butterfat. The rat on the left is of the same age, but has been stunted, due to a lack of the vitamin. Also, it is nearly blind. (From Steenbock and Hart, Wisconsin Station.)

192. Functions of vitamin A; effects of deficiency.—One of the chief functions of vitamin A is to keep the mucous membranes of the body healthy, so they will resist infection. A lack of the vitamin is especially apt to cause disease of the respiratory system. For example, calves and pigs fed rations deficient in vitamin A often die from pneumonia. A serious deficiency also injures the nervous system and may cause a staggering gait and finally spasms or paralysis.

One of the first symptoms of vitamin A deficiency is night blindness, or inability to see in dim light. This effect is produced because vitamin A is a part of the substance called visual purple, which is necessary for vision in dim light and which is partly used up through the action of light. Animals which are night blind recover when supplied with an ample amount of vitamin A.

More serious types of blindness are also caused by a lack of vitamin A. Thus, calves suffering from a severe deficiency of the vitamin may become blind, because of constriction of the optic nerves where they pass through the skull.[2] In other types of blindness, the cornea of the eye becomes cloudy and opaque, and the eye membranes are so changed that bacteria invade the eye and cause ulceration.

In calves common symptoms of a deficiency are poor growth, cold in the head with nasal discharge and sometimes

with a cough, and also scours. If the deficiency is continued, the calves usually succumb to pneumonia or other respiratory diseases. In fattening cattle kept for a long time on a ration deficient in vitamin A, a characteristic symptom of deficiency is dropsical swelling of the legs, known as anasarca.[3]

The so-called "cottonseed-meal poisoning" produced when cattle are fed for a long time on such a ration as cottonseed meal and cottonseed hulls, is due primarily to deficiency of vitamin A. (811) It can readily be prevented by feeding hay, silage, or other roughage that supplies sufficient carotene.

In chickens symptoms somewhat resembling roup often develop, with a sticky or cheesy discharge from the eyes and a sticky discharge from the nostrils.

A severe lack of vitamin A prevents successful reproduction. Females fed rations seriously deficient in vitamin A may not conceive, and if they do, the young are usually born dead or so weak that they perish.[4] A long-continued severe deficiency of vitamin A may affect the fertility of male animals and may cause degeneration of the sperm-producing cells. However, other symptoms of vitamin A lack are usually produced in males, before their fertility is impaired.

That disastrous results due to a lack of vitamin A may occur in livestock, even when they are on range pasture, is shown in a striking manner by California investigations.[5] During the dry season in some of the range districts of that and certain other western states, no green feed may be available for several months. The stock must then live on dry and bleached grass and other forage, which has practically no vitamin A value.

Often the cows abort, or the calves are born dead or so weak that they soon die. After calving, the cows may fail to come in heat until green feed is again available. Young cattle also suffer seriously, showing a general unthrifty appearance, intermittent diarrhea, and respiratory infections. If exposed to bad weather, such animals usually die from pneumonia. Unless the animals have been too seriously affected, they recover when supplied with feed rich in vitamin A value, such as fresh green forage or good quality alfalfa hay.

Animals are able to store considerable amounts of vitamin A in their livers and other tissues when they receive a liberal supply. Therefore, the length of time it will take for a lack of the vitamin to produce injurious results will depend on whether or not the animals have a store in their bodies at the start. Because of their greater requirements for vitamin A, young animals suffer from a deficiency much sooner than those which are mature. In Texas studies beef calves 3 to 5 months of age showed symptoms of night blindness in 56 days on the average, when fed a vitamin A deficient ration, while it took about 6 months for the symptoms to develop in yearling steers.[6]

Young mammals are born with only a small store of vitamin A in their bodies, even when their mothers have a liberal supply in their feed. However, colostrum, or the first milk, from well-fed animals is especially rich in vitamin A value. (270) This is one reason why it is so important that new-born mammals receive the colostrum. Investigations with cows, goats, and sows have shown that the vitamin A value of the colostrum milk, and in some cases even the store in the young at birth, can be increased by a very high intake of vitamin A or carotene during the latter part of pregnancy.[7]

193. Vitamin A and carotene.—Experiments have shown that vitamin A, which is nearly colorless, does not occur as such in plant products. However, all green-leaved parts of plants contain certain yellow-colored compounds, classed together as carotene, which animals can convert into vitamin A. Carotene is changed into vitamin A in the wall of the small intestine, and possibly to a small extent in the liver and other tissues.

The chief form of carotene in most green-leaved plants is beta-carotene. Other forms, called alpha-carotene and gamma-carotene, also occur in smaller amounts in plants. The vitamin A value of yellow corn is due chiefly to its content of cryptoxanthine, a closely related

compound. It is of interest that beta-carotene has twice as high a vitamin A value as do the other forms, because two molecules of vitamin A can theoretically be formed from each molecule of beta-carotene. Only one molecule of vitamin A can be made from each molecule of the other compounds. Still other compounds from which vitamin A can be formed have been found in algae and bacteria. These are not of importance in stock feeding.

Not all yellow pigments in plants have a vitamin A value. For example, xanthophyll, which occurs along with cryptoxanthine and carotene in yellow corn, has none.

Those foods of animal origin that possess vitamin A value may contain both the colorless vitamin A and also yellow carotene. In the white milk from Holstein or Ayrshire cows there is more vitamin A and less carotene than in the yellow milk from Guernseys or Jerseys. The difference is due to the fact that Holsteins and Ayrshires convert the carotene from their feed more completely into vitamin A. (**1043**)

The vitamin A value of fish-liver oils and other fish oils is due to vitamin A and not carotene. It is of scientific interest, but not of practical importance, that some of the vitamin A in fresh water fishes differs in structure from ordinary vitamin A. This form is called vitamin A_2, and sometimes the ordinary form is designated as vitamin A_1 to distinguish it from the uncommon form.

194. Vitamin A and carotene requirements.—Because of the importance of vitamin A and carotene for livestock, the requirements of each class of stock are considered in the respective chapters of Part III. The amounts of carotene advised for the various animals, except poultry, are stated in the Morrison feeding standards. (Appendix Table III.) The vitamin A requirements of poultry are stated in Chapter XXXVI.

The amounts of carotene recommended for the various animals in Appendix Table III are stated in terms of milligrams of carotene needed per head daily. (1,000 milligrams equal 1 gram, and about 28,000 milligrams equal 1 ounce, avoirdupois.) Appendix Table V shows the average carotene content of the most important feeds, stated in terms of milligrams per pound of feed and also in U.S.P. units per pound.

The total vitamin A value of a feed or ration is stated in U.S.P. units of vitamin A activity. The new U.S.P. unit is the vitamin A value for rats, used as test animals, of 0.30 microgram of pure vitamin A alcohol, or of 0.60 microgram of pure beta-carotene. The U.S.P. unit is the same as the revised International Unit (I.U.).

The relative value of a microgram of carotene and of vitamin A differs considerably for various animals. For rats 0.6 microgram of carotene is equal in value to 0.3 microgram of vitamin A (1 U.S.P. unit). However, the weight of carotene required by calves is 5 or more times the amount of vitamin A needed.

The carotene or vitamin A content of feeds is commonly determined by colorimetric or spectroscopic methods. The total vitamin A value may be measured also in growth tests with young rats.

195. Carotene and vitamin A readily destroyed.—Both carotene and vitamin A are readily destroyed by oxidation. For this reason a great loss of vitamin A value occurs in the ordinary making of hay from green forage. A considerable loss also takes place when dry roughage or a concentrate mixture containing vitamin A is stored for too long a period.

Hay which is made in good weather by modern methods and which is leafy and green in color will still be rich in carotene, though much lower on the dry basis than the green crop from which it was made. On the other hand, hay that is decidedly bleached or weathered will be low in carotene. If hay heats or molds badly in curing or in storage, practically all of the carotene may be lost.

The rate of loss of carotene in hay during storage depends largely on the temperature. The loss is rather rapid in summer and very slow in cold winter weather. In storage, the carotene may be

lost from hay more rapidly than the green color.

There is much less loss of carotene when a hay crop is made into silage by a suitable method than when it is cured into hay in the ordinary way. The loss is still less when the crop is artificially dried, or dehydrated, because of the rapidity with which the plants are dried. However, even in artificially dried hay, such as dehydrated alfalfa meal, a continual loss occurs during storage at ordinary temperatures, unless some means is used to reduce the loss.

The relative losses of carotene in field-cured hay, dehydrated hay, and hay-crop silage are well shown by extensive Vermont experiments.[8] On the average, field-cured hay made in good weather had 42 per cent as much carotene, on the dry basis, when it was stored in the barn, as there was in the green crops when cut. After storage for 6 months the carotene content was only 11 per cent of the original amount, and after a year only 9 per cent.

Dehydrated hay lost but little carotene in the drying process, and after 6 months of storage it still had 57 per cent of the original content. When the crops were made into silage with the addition of molasses as a preservative, the carotene was also retained well. At the time the silage was fed in winter, it still had about 42 per cent as much carotene as there was in the green crops when ensiled.

The vitamin A value of whole yellow corn is retained fairly well in storage. In Iowa tests yellow shelled corn which had been stored for more than a year had three-fourths as much vitamin A value as corn of the previous year's crop, and corn that was 4 years old had about one-half as much.[9]

Large losses of carotene and vitamin A occur in ordinary concentrate mixtures which are stored under usual conditions for any long period.[10] Except in very hot weather, the loss is not serious during storage for 4 to 6 weeks, but one-half or more of the vitamin A value may be lost in 6 months. The presence of rancid fats greatly increases the loss, and the loss is also more rapid when the mixture contains meat scrap, tankage, dried dairy by-products, or certain mineral supplements.

Methods have been developed for reducing the loss during storage of vitamin A in alfalfa meal and in vitamin A supplements added to feed mixtures. Some producers of alfalfa meal store part of their product in tanks in an atmosphere free of oxygen or under refrigeration, in order to retain the carotene content. This alfalfa meal is then mixed with that from ordinary storage, so that a definite carotene content can be guaranteed at any time of the year.

The loss of carotene in alfalfa meal or of carotene and vitamin A in a feed mixture can also be reduced by the addition of a suitable antioxidant.[11] Methods have been devised for stabilizing the vitamin A value of special vitamin A supplements by coating the particles with gelatin or wax, or by adding an antioxidant.

196. Carotene content of roughages.—The approximate amounts of carotene in various roughages and other feeds are given in Appendix Table V. One of the most important facts in stock feeding is that all green parts of growing plants are rich in carotene and hence have a high vitamin A value. Stock on good pasture therefore always have plenty of the vitamin. In green plants the yellow color of the carotene is masked by the green color of the chlorophyll.

The green leaves of plants contain much more carotene than the stems. For example, alfalfa leaves may contain 4 to 6 times as much as the alfalfa stems.[12] For this reason alfalfa leaf meal is higher in carotene than alfalfa meal made from the entire hay. Alfalfa stem meal is relatively low in carotene.

Forage plants generally have the most carotene, on the dry basis, at early stages of growth, and the amount decreases as the forage becomes older. Therefore the content is much lower at the hay stage of growth than at early pasture stages. When plants mature, the carotene decreases greatly, and but little

is left when they become dry and weathered.

While actively growing plants are always rich in carotene, mature, weathered pasture forage may have so little that animals kept too long on such feed alone may suffer severely from vitamin A deficiency. If parts of the plants remain green, these parts will retain some carotene. It was found in New Mexico studies, for example, that black grama grass kept some carotene content during the dry season much better than other range grasses, because the lower parts of the stems remained green.[13]

Investigations have shown that at an immature pasture stage some of the grasses are fully as rich as alfalfa or other legumes in carotene, on the dry basis.[14] Dehydrated grass made from young plants may be as rich in carotene as dehydrated alfalfa.[15]

The relative amount of carotene in any particular lot of hay can usually be estimated roughly from its color and its leafiness. The Federal Hay Grades are therefore generally good indications of the vitamin A value of various lots of hay. However, on long storage the carotene content may be mostly lost, while the hay still is green.

In Michigan studies the carotene content was determined in many samples of legume and mixed hay taken from farmers' barns during the winter feeding season.[16] The average carotene content of the samples of hay that graded U.S. No. 1 was more than twice as high as that of the samples which graded U.S. No. 3.

Legume hay usually has decidedly more carotene than grass hay of equal quality, due in part to the greater proportion of leaves. Soybean hay is generally lower than alfalfa hay in carotene. Straw of all kinds has but little carotene.

Dehydrated or sun-cured alfalfa meal is the most common carotene supplement in poultry rations and is also widely used for other animals when additional vitamin A is needed. (417) Unfortunately, the carotene content of alfalfa meal, even dehydrated alfalfa meal, varies greatly on our markets. This is shown by the analyses reported by the feed inspection services in various states. Some alfalfa meal has had no more carotene than fair hay.

In buying alfalfa meal, it is therefore important to purchase a product that has a carotene content guaranteed by the manufacturer.

Corn forage is rich in carotene when the plants are still green, but the content decreases rapidly as they mature. The carotene value of corn silage varies widely, because of difference in maturity and in extent of loss in the ensiling process. Per pound of dry matter, good corn silage, made from corn harvested before the lower leaves have turned brown, may be as rich in carotene as well-cured hay.

Sorghum silage tends to be lower than corn silage in carotene. This is partly because in this country corn silage is usually made from yellow varieties of corn, and yellow corn grain has considerable carotene value. Sweet sorghum silage generally has more carotene than silage from grain sorghum, probably because it has a greater proportion of leaves.[17]

Silage made from alfalfa or other hay crops is especially high in carotene, on the dry basis, if it is well preserved. (437) Per pound of dry matter, it usually has much more carotene than first-rate hay.

197. Carotene or vitamin A content of concentrates.—With the single exception of yellow corn, the cereal grains have practically no carotene. Yellow corn is an important source of carotene, though it usually contains only one-tenth to one-quarter as much as good legume hay.

The vitamin A value of yellow corn is due to its content of both beta-carotene and the closely-related cryptoxanthine. Xanthophyll, which forms a considerable part of the coloring matter in yellow corn, has no vitamin A value. In general, the deeper the yellow of corn grain, the greater will be the vitamin A value, though there are some exceptions. Corn gluten feed, corn gluten meal, and

hominy feed made from yellow corn are somewhat higher than the whole grain in carotene.

Ripe peas of green varieties equal yellow corn in carotene content, but mature soybean or cowpea seed has but little carotene. Millet seed supplies some carotene.

With the exception of carrots and yellow sweet potatoes, roots and tubers probably supply no appreciable amounts of carotene. In carrots and sweet potatoes carotene is highest in the varieties having the deepest yellow color. Yellow pumpkins and yellow-fleshed squash have considerable carotene.

Among human foods whole milk, butter, and all other dairy products containing the butterfat are perhaps the most important sources of vitamin A. In raising dairy calves on milk substitutes, it is necessary to continue the feeding of whole milk until the calf is old enough to eat considerable hay, or else to include a vitamin A supplement in the milk substitute.

If cows or other lactating animals have been fed for a considerable time on rations deficient in vitamin A value, the content in the milk will be low. The effect of the ration upon the vitamin value of milk and butter is discussed in detail in Chapter XXV, and also the effect of the breed of cow on the vitamin A value and the color of milk and butter. (1043–1044)

Practically all the vitamin A value in milk is present in the butterfat. Therefore skimmilk and other milk products from which nearly all of the fat has been removed will have but little of the vitamin. Indeed, skimmilk may contain only one twenty-fifth as much vitamin A value as whole milk.[18]

LACK OF VITAMIN A DISASTROUS TO PIGS

Above: Pigs fed white corn and skimmilk with alfalfa hay to furnish vitamin A value. All made good gains and remained thrifty.

Below: Pigs fed white corn and skimmilk without vitamin A supplement. Four of the pigs had already succumbed because of the lack of vitamin A. Those which had a greater store of the vitamin at the start survived, but they made unsatisfactory gains. (From Wisconsin Station.)

The yolks of eggs from properly fed poultry are rich in vitamin A, and liver is also an excellent source. Tankage and meat scrap supply little or no vitamin A. If fish meal has not been processed at too high a temperature, it will usually supply some vitamin A. However, the content is so variable that reliance cannot be placed upon it as a source of the vitamin, unless the source and method of manufacture are definitely known. Cod-liver oil and other fish-liver oils are

the richest natural source of vitamin A, and other fish oils are also generally rich in it. The amount of vitamin A in the liver oils from sharks, swordfish, tuna, and certain other species is many times as great as in cod-liver oil.

198. Meeting the vitamin A needs.—In the discussions on vitamin A for the various kinds of animals in Part III, it is shown that it is not generally necessary to use any special vitamin A supplement for dairy cows, beef cattle or sheep, or horses. Their vitamin A needs can be fully met by the use of good roughages, fed as there advised.

On the other hand, poultry not on excellent pasture need additional vitamin A. This is supplied by including alfalfa meal in the mash to furnish carotene, or by adding a vitamin A supplement. Also, for swine not on pasture it is important to include in the ration good quality sun-cured legume hay to provide both vitamins A and D, or else to use a special A-D supplement. Likewise, a vitamin A supplement should be included in a milk substitute for dairy calves weaned from milk at a very early age.

In addition to alfalfa meal, which has been discussed previously, various concentrated vitamin A supplements are produced commercially. Concentrates supplying both vitamin A and vitamin D are made from cod-liver oil and certain other fish oils. In addition, carotene concentrates are produced from dehydrated alfalfa or vegetable wastes, and synthetic vitamin A is made on a large scale. The vitamin potency of these products is guaranteed by the manufacturer.

III. Vitamin D

199. Vitamin D, its functions and importance.—It has been shown in the previous chapter that an adequate supply of vitamin D is necessary for the proper assimilation and use of calcium and phosphorus and the development of good bones and teeth. This vitamin is just as necessary as are ample amounts and proper proportions of these two minerals. Since vitamin D is necessary for the prevention of rickets in young animals, it is often called the anti-rachitic vitamin. Vitamin D is soluble in fat and is therefore one of the fat-soluble vitamins.

The requirements for vitamin D are especially great during growth, when the skeleton is being developed. For mere maintenance, mature animals need much less vitamin D, but more is required during pregnancy and for milk production.

Animals need more vitamin D than normal when there is insufficient calcium or phosphorus in the ration, or when the proportion between the amounts of these minerals is not the most suitable.

The requirements for vitamin D by different species of animals differ widely. Poultry require more vitamin D in their rations than do other farm stock, and the requirement is especially high for egg production. Turkeys need even more vitamin D than do chickens. At the other extreme are foxes and minks, which apparently need no vitamin D when there are optimum amounts of calcium and phosphorus in their diet and also an optimum calcium-phosphorus ratio. White pigs, at least of certain breeds, seem to need very little vitamin D under similar conditions, even when exposed to no direct sunlight.

Animals are able to store some vitamin D in their bodies, chiefly in the liver, when they receive more than their minimum needs, but such storage is relatively small in comparison with the storage of vitamin A. In South Dakota experiments mature dairy cows did not usually show definite symptoms of vitamin D deficiency until after 4 to 10 months, when they were fed a ration devoid of the vitamin and were allowed no exposure to sunlight.[19] Young animals show a lack of vitamin D much sooner. For example, new-born lambs are protected against a deficiency by the store in their bodies for only about 6 weeks.

The requirements of each class of stock for vitamin D are considered in detail in the respective chapters of Part III. It is there shown that generally

there is no need of supplying farm animals with special vitamin D concentrates, except in the case of poultry, and also under certain conditions, dairy calves and swine.

Fortunately, as is shown later in this chapter, sunlight is an effective source of vitamin D for animals, and hay and other dry roughages cured in the sun supply considerable amounts. These sources usually provide adequately for the needs of dairy cows, beef cattle, sheep, and horses. In the colder climates, where swine are not outdoors much in winter, sun-cured legume hay of good quality should be provided if possible, as insurance against lacks of vitamin D or vitamin A. When this cannot be done, a special vitamin A-D supplement should be fed. Vitamin D supplements are commonly needed for poultry, except when they are exposed to plenty of direct sunlight.

If dairy calves are supplied good sun-cured legume or mixed hay as soon as they will eat it, they will usually have sufficient vitamin D. However, as insurance against any possible deficiency, many feed manufacturers include a vitamin D supplement in their calf starters.

In recent Ohio experiments, summarized in Chapter XXVI, cases of milk fever in dairy cows have been lessened by feeding very large doses of vitamin D supplement for a week before calving. (1086) Such large doses cannot be given an animal for any long period without injury.

Vitamin D was discovered in 1922 by McCollum of Johns Hopkins University, who found by passing heated air through cod-liver oil to destroy vitamin A, that it contained a second vitamin which prevented and cured rickets. This was named vitamin D.

The discoveries concerning the functions and sources of vitamin D since that time have been of great value to humans and also to the livestock industry. By using the information now available, stockmen can readily prevent the disastrous results from rickets that were once common, especially in poultry, pigs, and dairy calves.

200. Effects of deficiency of vitamin D.—A serious deficiency of vitamin D in young animals causes rickets, the symptoms of which have been described in the previous chapter. (153) A lack that is not severe enough to cause visible symptoms of rickets may retard growth and result in a weak skeleton, impaired joints, and poor teeth.

Pregnant animals suffering from a severe deficiency of vitamin D will not only produce young which are weak and are subject to rickets, but sometimes the young are born with malformations. Also, the skeleton of the mother is injured by the deficiency.

In mature fowls a deficiency of the vitamin causes thin-shelled eggs, decreased egg production, and lowered hatchability. The breast bone may become soft and rubbery, and the bones of the wings and legs fragile and easily broken.

201. Nature of vitamin D and its relation to light.—Vitamin D is formed by the action of sunlight or other light that contains ultra-violet rays upon a compound called ergosterol and also upon certain other sterols, which are similar compounds. Small amounts of ergosterol occur in most common foods and stock feeds, and traces of the other sterols which can be changed into vitamin D are present in animal tissues. These sterols have no vitamin D effect before they are changed into vitamin D.

The fact that ultra-violet light produces vitamin D in foods was discovered nearly simultaneously by Steenbock of the University of Wisconsin and Hess of Columbia University.

When green forages are field-cured into hay or dry fodder, vitamin D is formed from ergosterol through the action of the ultra-violet light in sunlight. The green, growing parts of plants contain ergosterol, but little or no vitamin D.

Vitamin D is similarly produced when foods are artificially exposed to ultra-violet light. Irradiation for too long a time will destroy some of the vitamin D that has been produced. As yeast contains considerable ergosterol, irradiated

dry yeast, which is extremely rich in vitamin D, is produced commercially by the irradiation of yeast with ultra-violet light.

Sunlight is an effective source of vitamin D for animals, because the ultra-violet light in the sun's rays converts the small amounts of sterols in the skin and the skin secretions into vitamin D. Even the vitamin formed in the skin secretions, outside the skin itself, can be absorbed into the body. Some of the vitamin formed on the skin is also taken into the body when animals lick themselves.

The ultra-violet rays in sunlight are absorbed to some extent as they pass through the atmosphere, before reaching the earth. Therefore the greater the distance that the sun's rays have to travel through the earth's atmosphere, the less is the content of ultra-violet light and the anti-rachitic effect. Sunlight is thus more potent in the tropics and at high altitudes in mountains. Also, the anti-rachitic effect is much greater at noon than early or late in the day, when the rays are very slanting. Similarly, in the temperate zones it is much greater in the summer than in winter. The ultra-violet rays are largely screened out by clouds or smoke. The anti-rachitic effect is hence less in regions where there is a great amount of cloudy weather, or where the air is commonly very smoky.

If sunlight passes through ordinary window glass, practically all the ultra-violet rays are removed. Such light does not therefore have an anti-rachitic effect. Some special kinds of glass and also certain glass substitutes permit the passage of more or less of the ultra-violet rays.

During the growing season stock that are out in the sunshine much of the time generally get ample vitamin D through the effect of sunlight on their bodies. Even in winter, exposure to sunlight has considerable anti-rachitic effect. For example, in Minnesota experiments pigs suffering from rickets caused by a lack of vitamin D recovered to a marked degree when exposed to sunlight in winter for only 45 to 90 minutes a day.[20]

When stock are exposed but little to sunlight that has not passed through ordinary window glass, it is necessary to give attention to their vitamin D requirements. However, it is not necessary for the animal to be in direct sunlight to receive some ultra-violet rays. Owing to the reflection of the ultra-violet light, the indirect light from "sky shine" on a clear day has considerable anti-rachitic effect.

Animals with black or dark hair or skin secure less vitamin D from sunlight than do animals with white or light-colored hair. This is because more of the ultra-violet rays are absorbed by the hair or skin before they penetrate into the tissues. For this reason, white pigs are less subject to rickets than black or dark pigs, when kept under similar conditions.

Although livestock on pasture are usually protected from rickets by the ultra-violet rays in sunlight, rickets in lambs on pasture sometimes occurs in New Zealand for some unknown reason.[21] The trouble can be prevented by administering vitamin D.

202. Relative value of different forms of vitamin D.—Two forms of vitamin D are important. The first is vitamin D_2, which is the form produced by the action of ultra-violet light upon ergosterol, the plant sterol. The other is vitamin D_3, which is produced by the effect of ultra-violet light upon a sterol (called 7-dehydrocholesterol) that occurs in small amounts along with cholesterol in animal tissues. (14) There are also other forms of vitamin D that are not important.

Vitamin D_3, also called activated animal sterol, and sold under the name of Delsterol, is made commercially from animal sterols, by irradiation with ultra-violet light. Vitamin D_3 is believed to be the chief form of vitamin D occurring naturally in cod-liver oil and most other fish oils.

A certain amount of vitamin D potency can be produced by treating certain sterols chemically, but such chemical methods of making vitamin D supplements have not yet been developed commercially.[22]

Vitamin D_2 and vitamin D_3 have approximately the same value for all four-footed animals and also for human beings. Rats are therefore used as test animals to determine the potency of any product in vitamin D for such animals. (No accurate chemical method for measuring vitamin D has yet been developed.)

Vitamin D_2, which is the form in irradiated yeast and in sun-cured forage, is much less effective for poultry than it is for four-footed animals or for human beings. Indeed, it may take 40 times as much, or even more, of vitamin D_2 to protect chicks against rickets as it does of vitamin D_3. The value of various products as sources of vitamin D for poultry is therefore found in tests with chicks.

Vitamin D potency is measured in terms of International Units (I.U.) of the vitamin. In the recently revised international standard, one I.U. of vitamin D is equal in potency to 0.025 microgram of pure crystalline vitamin D_3. For poultry, the vitamin D requirements and vitamin D values of feeds are expressed as International Chick Units (I.C.U.) to differentiate between vitamin D_3 and vitamin D_2 value.

The new unit, which is equally potent for chicks and other animals, replaces the two standards formerly used—the A.O.A.C. chick unit, based on vitamin D_3 potency, and the old I.U., based on vitamin D_2, for other kinds of stock.

203. Stability of vitamin D.—Both common forms of vitamin D (D_2 and D_3) are much more stable than vitamin A or carotene. They are not readily destroyed, even by heating in the air at a temperature much above the boiling point of water. When vitamin D supplements are mixed with the usual kinds of poultry mashes or other concentrate mixtures, the vitamin D potency is usually retained well during storage for some months, even in summer. The vitamin D value of sun-cured hay or other forage is also retained well on storage.

However, rather rapid loss of vitamin D value may occur if a vitamin D supplement is combined with minerals, especially calcium carbonate, or with dried milk products, as a premix to be added later to a poultry mash or other concentrate mixture. The potency of some dry vitamin D supplements is also apparently lost rather rapidly on storage.

204. Vitamin D content of feeds.—Among the common livestock feeds the only important sources of vitamin D are hay and other roughages that have been sun-cured, or that have had some exposure to sunlight, as in making barn-dried hay or wilted grass silage. The vitamin D in field-cured roughages is vitamin D_2, and therefore has a very low value for poultry.

There is as yet relatively little information available concerning the amounts of vitamin D in the various kinds and grades of hay and other dry forages, because of the difficulty and expense in making vitamin D determinations. The approximate vitamin D content in various feeds is stated in Appendix Table Vc, so far as data are available.

The data thus far published show that the amount of vitamin D, even in sun-cured hay, varies widely.[23] However, in a New York study samples of various kinds of hay, taken from farmers' barns during the winter feeding season, all had 450 I.U. or more of vitamin D per pound, the average for 14 lots of hay being 854 I.U. per pound.[24] Only 3 lbs. of hay containing 500 I.U. per pound will meet the vitamin D needs of a 500-lb. calf, which is housed in a stable where it has no exposure to sunlight.

Differing from the carotene content, the amount of vitamin D may be as high in hay that is of lower quality, because of injury from bad weather during curing, as in first-quality hay that is very green in color.

In field-cured hay, the leaves have much more vitamin D than do the stems. Probably leafy hay is usually higher in vitamin D than stemmy hay. However, a high content of 748 I.U. per pound has been reported for wheat straw.

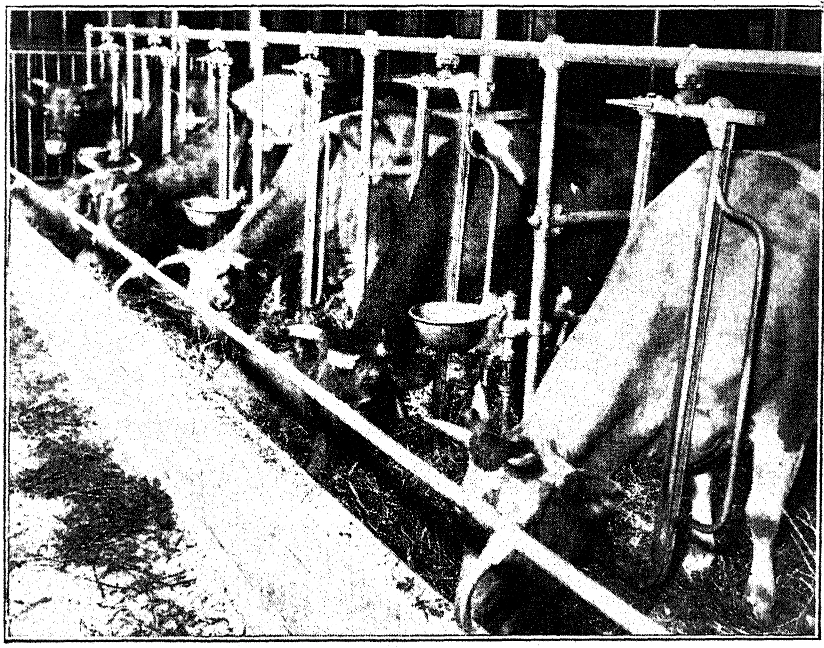
Information is insufficient to draw definite conclusions about the relative vitamin D content of various kinds of

field-cured hay, but grass hay seems to be somewhat lower, as a rule, than legume hay.

It has been generally believed that the green, growing parts of plants have little or no vitamin D, and that it is formed only during the sun-curing process by the action of the ultra-violet rays. However, leaves or stems that had died or were brown have been found to have considerable vitamin D.

content varies so widely that it cannot be relied on as a source of this vitamin. As has been stated previously, dehydrated hay is used primarily as a carotene supplement.

In experiments by the United States Department of Agriculture, wilted alfalfa silage or barn-dried alfalfa hay, fed at the usual rates, had plenty of vitamin D to prevent any symptoms of rickets in dairy calves housed in the dark



FIELD-CURED HAY FURNISHES VITAMIN D

Hay cured in the sun is an effective source of vitamin D for all livestock except poultry. Other field-cured roughage, such as corn fodder or straw, also supplies considerable vitamin D.

In a recent Vermont experiment it was found that green leaves which were hand-picked from hay plants and then cured in a dark barn away from sunlight, nevertheless had considerable vitamin D.[25] Also, in other trials some dehydrated alfalfa hay has had so much vitamin D that rickets could not be produced in dairy calves fed the hay and kept away from all sunlight.[26] Though dehydrated hay may sometimes have an appreciable amount of vitamin D, the

away from the sunlight, even though the calves had first been depleted of the vitamin before the experiment began.[27] Similar results were secured in Vermont trials with barn-dried hay.[28]

Corn silage ensiled at the dent stage, when the lower leaves had become dry, contained 40 International Units per pound on the average in Michigan studies.[29] The vitamin D content was almost entirely in the dried parts—the lower leaves and the tassels, husks,

and silk—for the green leaves had practically none.

An important fact in stock feeding and also in human nutrition is that none of the cereal grains or other common seeds contains any appreciable amount of vitamin D. Indeed, cocoa shells are the only seed by-product that has been found to have any significant amount of the vitamin. It is apparently formed in cocoa shells through the exposure of the cocoa beans to the tropical sunlight in the curing process.

The livers of fish are strikingly rich in vitamin D, and also the body oils of most fish contain considerable amounts. For this reason cod-liver oil and certain other fish oils are used as vitamin D supplements for infants and for poultry or other animals. Clams and oysters contain some vitamin D.

Fish meal is variable in vitamin D content, some fish meals being a fair source and others containing but little. The content depends on the source of the raw material and on the degree of heat used in the process of manufacture.

Meat scrap and tankage supply no appreciable amounts of vitamin D. In general, meat from mammals contains practically none of the vitamin, except from such organs as the liver and kidneys, which may have limited amounts. In contrast, the yolks of eggs from poultry receiving ample vitamin D are rich in the vitamin.

205. Vitamin D supplements.—Because of the richness in vitamin D as well as vitamin A, cod-liver oil and certain other fish-liver oils and fish-body oils are used as vitamin D supplements. The vitamin content is commonly guaranteed by the manufacturer. At present concentrated vitamin D supplements are in more general use.

By removing the true fat or oil (which contains no vitamins) from cod-liver oil or other fish oils, vitamin concentrates are prepared which are much more potent than the original fish oils. These supply both vitamin A and vitamin D (vitamin D_3) and are commonly sold with definite guarantees of vitamin value.

Irradiated yeast, produced by treating yeast with ultra-violet light, is an effective vitamin D supplement for humans and for four-footed animals. As has been previously stated, it has a low potency for poultry. Various types of irradiated yeast are made with guaranteed potencies ranging from 4,000,000 to 64,000,000 International Units of vitamin D_2 per pound.

In the production of the product known as viosterol, or calciferol, the ergosterol is separated from yeast and then irradiated. This gives a product still more potent in vitamin D_2 on the dry basis.

Activated animal sterol, or irradiated cholesterol, which supplies vitamin D_3, is used extensively as a vitamin D supplement for poultry. The vitamin potency is guaranteed in terms of International Chick Units (I.C.U.) of vitamin D, and a common guarantee is 900,000 units per pound.

206. Vitamin D in milk; vitamin D milk.—Whole milk from cows fed normal rations contains a significant, though relatively small, amount of vitamin D, and milk and butterfat are of considerable importance as sources of the vitamin for man. The vitamin D content of normal milk ranges from 3 to 56 International Units per quart. Summer milk usually has considerably more than winter milk, because of the exposure of the cows to sunlight. Skimmilk and other dairy products containing but little butterfat have only traces of the vitamin.

There is apparently little difference in the vitamin D content of the butterfat in the milk of the various breeds of cows. Because Guernsey and Jersey milk is rich in fat, it supplies somewhat more of the vitamin than milk lower in fat. If cows are fed a ration low in vitamin D and are not exposed to sunlight, their milk will be lower than normal in the vitamin.

Even summer milk does not supply enough vitamin D to protect infants fully against rickets, if they receive no other source of the vitamin. Therefore vitamin D milk, usually containing not less than 400 International Units of the vitamin

per quart, is produced commercially. The most common method now is to add a vitamin D concentrate to the milk. The vitamin D content of milk can also be increased by irradiating the cows with ultra-violet light, or by feeding them irradiated yeast. When cows are fed irradiated yeast, a very high intake is needed to raise the vitamin D content of the milk to the desired level.

It is pointed out in Chapter XXV that when cows are fed ordinary good rations and have the normal amount of exposure to sunlight, they are not benefited by feeding them a vitamin D supplement. (**1046**)

207. Effect of cod-liver oil on herbivora.—Cod-liver oil has been widely used as a satisfactory vitamin supplement for humans and for poultry. However, when cod-liver oil is given to herbivora for long periods, injurious results may be produced. For example, in New York experiments fatal results were produced when sheep, goats, rabbits, or guinea pigs were fed cod-liver oil for a long time, even though the amounts of cod-liver oil were not excessive.[30] In these animals there was a degeneration, or dystrophy, of various muscles, including the heart, in some cases. Similar injurious results to calves and other animals have also been reported by other investigators. The bad results may have been due to destruction of vitamin E caused by the cod-liver oil. When fed to cows or goats, cod-liver oil and certain other fish oils also cause a marked decrease in the fat content of the milk. (**1064**)

Because of these results it does not seem wise to use cod-liver oil over long periods as a vitamin supplement for herbivora (including cattle, sheep, goats, and possibly horses). In the cases where it is advisable to add a vitamin supplement to rations made up of ordinary feeds for these classes of stock, it is apparently safer to use a vitamin concentrate instead.

IV. The B-Complex Vitamins

208. Vitamin B complex.—In the regions of the Orient where polished rice is the chief food of the people, the disease known as beri-beri was widespread until it was found that this disease was due to vitamin deficiency. The symptoms of the disease are loss of appetite, fatigue, depression, and other nervous disorders.

It was at first believed that beriberi was caused by the lack of a single vitamin, which was called vitamin B. It was found later that what was formerly thought to be one vitamin actually consists of separate vitamins that have different functions. The term "vitamin B complex" is now used for the group of vitamins included in what was formerly considered to be the single factor, vitamin B. All the vitamins in the vitamin B complex are soluble in water.

At least 10 B-complex vitamins have been discovered thus far, and there is some evidence that others exist. Some of these vitamins are widely distributed in ordinary livestock feeds, and therefore there is no lack of them in practical rations. Deficiencies occur only when farm animals are fed rations made up of purified nutrients under experimental conditions.

Fortunately, the various B-complex vitamins are synthesized by the bacteria in the rumen of ruminants.[31] An ample supply thus becomes available to the ruminant, even when there might be a lack in the feed itself. Deficiencies of these vitamins are therefore not apt to occur in the case of cattle, sheep, or goats, at least after the animals have reached an age when the rumen has become well developed. Occasionally, there may be a deficiency, if normal bacterial action does not take place in the rumen, because the animal is suffering from other nutritive lacks or is otherwise in poor health.

Considerable synthesis of B-complex vitamins occurs in the caecum and large intestine of the horse,[32] and a limited amount may also take place in the intestines of other animals. This may appreciably reduce the supply needed in the feed.

209. B-complex vitamins in livestock feeding.—Green forages have a

good supply of all of the B-complex vitamins, except vitamin B_{12}. It is surprising that although laboratory determinations have not shown any appreciable amounts of this vitamin in green, growing forage, nevertheless growing chickens on good pasture never seem to have a deficiency of the vitamin, although they definitely need it in their diet. Well-cured hay and good silage are undoubtedly good sources of most of the B-complex vitamins.

The amounts of the B-complex vitamins in important feeds are stated in Appendix Tables V, Va, and Vb, so far as data are available.

When dairy cows, beef cattle, or sheep receive ordinary rations that include satisfactory roughage, no attention need generally be given to the B-complex vitamins, because of the synthesis of these vitamins in the rumen. (44) A deficiency of B-complex vitamins can be produced in very young calves or lambs by feeding them highly purified diets containing no hay or even grain. However, when dairy calves are raised by the usual methods on natural feeds, there is generally no benefit from the use of vitamin pills or capsules to supply additional B-complex vitamins. (1120) Under natural conditions beef calves and lambs are well supplied with these vitamins.

Swine need the B-complex vitamins in their feed, because there is but little synthesis of them in their digestive tracts. Nevertheless, their requirements can be met if they are provided during the growing season with good pasture and if sufficient well-cured legume hay is included in their rations when they are not on pasture. However, for pigs not on pasture there may be an appreciable benefit from adding a B-complex vitamin supplement to the ration, especially a vitamin B_{12} supplement. Such additions to swine rations are discussed in Chapter XXXIV.

Poultry have such high requirements for riboflavin that it is necessary to include a riboflavin supplement in most rations, unless the birds are on good pasture. Some practical poultry rations are also deficient in vitamin B_{12} and certain other B-complex vitamins. The requirements of poultry for the B-complex vitamins and the use of supplements supplying them are therefore discussed in detail in Chapter XXXVI.

It has been reported that periodic ophthalmia, a perplexing disease that sometimes occurs in horses, may be prevented but not cured by a riboflavin supplement.

210. Yeast as a B-complex supplement.—Various forms of yeast, especially brewers' dried yeast, are sometimes used as a B-complex vitamin supplement for livestock. There is no advantage in adding yeast to usual well-balanced rations for dairy cows, dairy heifers, beef cattle, sheep, or horses, because they need no additional supplies of the B-complex vitamins.

There may be some benefit from including yeast in a calf starter for dairy calves raised on a minimum amount of milk, or in a milk substitute or replacer. (1119)

It does not usually pay to add yeast to rations for swine on pasture or even for those in dry lot which are fed good rations that include legume hay and a protein supplement of animal origin. For pigs in dry lot fed such a ration as grain, soybean oil meal, minerals, and a small percentage of alfalfa meal, there may be a benefit from including yeast, unless the ration has some other B-complex vitamin supplement.

Brewers' dried yeast furnishes some of the thus far unidentified vitamins needed by poultry. As shown in Chapter XXXVI, there is an advantage in adding yeast to certain rations for chicks and broilers, if sufficient amounts of these unknown vitamins are not supplied by the other feeds.

211. Thiamine.—Thiamine, which is also called vitamin B_1, prevents the polyneuritis (nervous symptoms) in beriberi and was therefore termed the antineuritic vitamin. A lack of thiamine also causes loss of appetite, failure to grow, emaciation, general weakness, and finally death. Thiamine is an essential part of an enzyme needed for the metabolism

of carbohydrates in the body, and is apparently required by all species of animals.

Thiamine is widely distributed in natural human foods and stock feeds. The unmilled cereal grains are all rich in it, nearly all the thiamine being in and adjacent to the germ and in the aleurone layer. Therefore white flour and polished rice have little. Fresh green forage contains a fair supply of thiamine, as do well-cured hay and other dry forage of good quality. It is supplied in fair amounts by milk and whey. Yeast is especially rich in it. Pure thiamine is produced commercially in considerable amounts by chemical synthesis for use chiefly as a vitamin supplement for humans.

The amounts of thiamine in important feeds, expressed in milligrams of thiamine per pound, are given in Appendix Table V, so far as data are available.

Thiamine is stable in ordinary dry feeds. For example, whole rice stored in an arid climate for 100 years was still rich in it. It is destroyed in neutral or alkaline solution by prolonged boiling.

It is of interest to note that when certain kinds of raw fish are included in the diet of foxes and minks, the thiamine is destroyed so completely that a form of paralysis is produced.

Because of the wide distribution of thiamine in common livestock feeds, farm animals undoubtedly secure ample amounts when fed any usual ration that would be otherwise satisfactory. Also, as has been stated previously, cattle and sheep are not dependent on a supply in their feed, because thiamine is synthesized by bacteria in the rumen.

The thiamine requirements of swine and poultry are stated in Chapters XXXIV and XXXVI.

Young Chick Paralyzed By Lack of Thiamine

This chick was fed an experimental ration lacking thiamine and is suffering from severe polyneuritis. (From Norris and Heuser, Cornell University.)

212. Riboflavin.—Riboflavin, which is also called vitamin B_2 and formerly vitamin G, was the second of the B-complex vitamins to be identified. Riboflavin is of much practical importance for poultry, which have high requirements for it. Their needs for riboflavin and the use of riboflavin supplements are discussed in detail in Chapter XXXVI.

Ruminants commonly have plenty of riboflavin in their usual rations. Also, it is fortunately synthesized in adequate amounts in the rumen, except for a few weeks after birth.

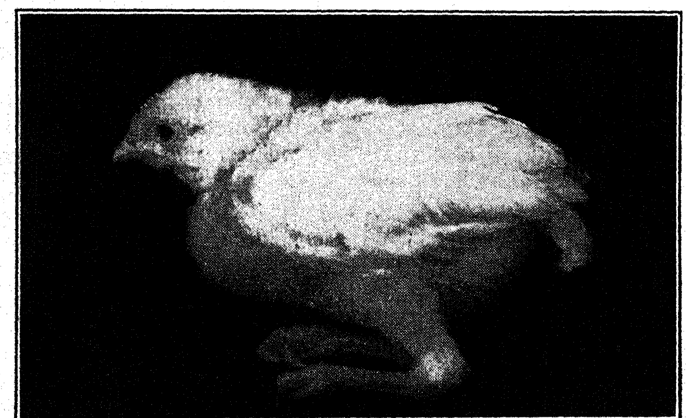
Swine on good pasture receive ample riboflavin, but the experiments summarized in Chapter XXXIV show that there is a benefit from adding a ribo-

flavin supplement to some well-balanced rations for pigs in dry lot.

Riboflavin is an essential part of an enzyme necessary in the oxidation processes of living cells and is therefore probably needed by all living cells. It is also a part of other important enzymes in the body. Riboflavin is essential for the growth of animals and for proper nutrition at all ages. A deficiency is apt to cause digestive disturbances, general weakness, poor condition of the eyes and skin, and nervous symptoms, as well as lessening the resistance to disease.

rich in riboflavin and liberal amounts are furnished by green forages, well-cured hay, and distillery by-products that include the distillers solubles. Whole grains and other seeds have significant amounts of riboflavin, but not enough to provide the chief source for poultry. Wheat bran and middlings supply considerably more riboflavin than does the entire wheat grain. The oil meals and also meat scrap, tankage, and fish meals have fair amounts.

Riboflavin supplements of three types are produced commercially. Syn-



RIBOFLAVIN DEFICIENCY IN A CHICK

Note the characteristic curled-toe paralysis. (From Poultry Husbandry Department, Cornell University.)

In chicks a deficiency of riboflavin causes a characteristic paralysis of the legs, called curled-toe paralysis. In hens a deficiency results in poor hatchability of eggs. A lack of the vitamin in pigs produces slow growth, stiffened legs, chronic diarrhea, skin eruptions, and eye troubles. Experiments, mentioned in Chapter XXXII, indicate that periodic ophthalmia, a perplexing eye disease that sometimes occurs in horses, may be prevented by the use of a riboflavin supplement.

Milk and dairy by-products, such as dried skimmilk, dried buttermilk, and dried whey, are especially rich in riboflavin. This is one of the chief reasons for the high value of milk by-products in poultry feeding. Yeast is also very

thetic riboflavin is manufactured chemically, and riboflavin concentrates are produced from bacterial cultures, or from certain fermentation residues in the production of butyl alcohol or other compounds. The riboflavin potency of these concentrates is guaranteed by the manufacturer. The riboflavin in all these types of supplements is equally available to animals, but it must be borne in mind that the synthetic riboflavin furnishes only this vitamin, while the other riboflavin supplements also supply some of the other B-complex vitamins.

213. Niacin, or nicotinic acid.—Niacin, or nicotinic acid, is a B-complex vitamin that is necessary for all animals, because it is a part of two important enzyme systems which are essential in

body metabolism. A supply in the food is, however, needed only by certain animals, including humans, swine, poultry, and dogs. A deficiency of niacin is the chief cause of pellagra, a serious disease of humans.

Ruminants, including cattle, sheep, and goats, do not need niacin in their food, because sufficient amounts are produced through bacterial synthesis in the rumen. (44) Certain other animals, including young calves, and also rats and horses, are apparently able to produce plenty of niacin in their tissues from other compounds.

Niacin is widely distributed in feeds, and ample amounts are supplied by most rations that are otherwise satisfactory. The requirements of swine and poultry, which in some cases are benefited by furnishing additional niacin, are discussed in Chapters XXXIV and XXXVI.

Recent investigations have proved that in the case of animals which require a food source of niacin, the vitamin can readily be made in the body from the amino acid tryptophan.[33] In this way tryptophan can replace niacin in the diet. This discovery explains why humans are more subject to pellagra when they live mostly on corn grain, which is very low in tryptophan, as well as being low in niacin. It also explains why there is more apt to be a deficiency in rations for pigs, when most of the feed is corn.

Experimental rations deficient in niacin cause lack of appetite in pigs, severe diarrhea, skin disease, and even paralysis of the hind quarters. It is pointed out in Chapter XXXIV that under practical conditions rations containing a liberal amount of niacin may reduce the trouble from necrotic enteritis in pigs. A lack of the vitamin in rations for dogs produces severe inflammation of the tongue and mouth, called black tongue. In chicks a deficiency of niacin causes a similar condition, and also slow growth, poor feathering, and sometimes a scaly condition of the skin. In young turkeys a lack produces a hock disorder, similar to perosis in chicks.

The amounts of niacin in important feeds are stated in Appendix Table V, so far as data are available. It will be noted that dried yeast, rice polish, rice bran, wheat bran, peanut oil meal, and green forage and pasture crops are rich in the vitamin. Barley grain, wheat grain, the sorghum grains, the oil meals, meat scrap, tankage, and fish meal are good sources. Good-quality hay supplies a fair amount, while corn grain, oats, rye, and dairy by-products have a rather low content.

Large quantities of niacin are now manfactured by synthetic chemical processes, chiefly for use in enriching bread and cereals and for other human use.

Niacin is stable in foods and is resistant to heat and oxidation. The vitamin occurs in foods not only as nicotinic acid, but also in the form of a compound called nicotinic acid amide, or nicotinamide, which is equally potent.

214. Pantothenic acid.—Pantothenic acid, earlier called the filtrate factor and the chick anti-dermatitis vitamin, is a B-complex vitamin that is needed by chickens, turkeys, pigs, dogs, foxes, and probably some other species of animals. Because of its wide distribution in feeds of both plant and animal origin, the rations commonly fed to livestock generally furnish ample amounts. It is also quite stable in feeds.

Rather restricted rations may occasionally have insufficient pantothenic acid for pigs and poultry. Therefore their requirements are discussed in later chapters. If ruminants need the vitamin, they do not require a supply in their feed, because it is synthesized by bacterial action in the rumen.

A deficiency of pantothenic acid, produced by restricted experimental rations, results in poor growth of chicks, ragged feather development, and skin disease (dermatitis), characterized by scabby sores at the corners of the mouth and on the feet, and incoordination and paralysis. In mature fowls a deficiency causes poor hatchability of eggs.

In pigs a deficiency of pantothenic acid causes poor appetite, slow growth, coughing, diarrhea, dermatitis, and stilted gait, known as "goose stepping." A lack

of pantothenic acid is one of the causes of premature graying of hair in rats, dogs, and foxes fed experimental rations deficient in the vitamin.

Large amounts of pantothenic acid are supplied by alfalfa hay and probably other good hay, by green pasture and grass crops, and by wheat bran, dairy by-products, peanut oil meal, rice bran, and cane molasses. Yeast is especially rich in the vitamin. Cereal grains and their by-products, most oil meals, beet pulp, and fish meal supply fair to good amounts. Calcium pantothenate, the calcium salt of pantothenic acid, is the pure form of the vitamin available commercially.

215. Pyridoxine.—Pyridoxine, or vitamin B_6, is a B-complex vitamin which is so widely distributed in common feeds that it is not deficient in ordinary rations for farm animals. By the use of experimental diets purposely made very low in pyridoxine, it has been found to be necessary for pigs, poultry, dogs, and rats.

A deficiency of the vitamin causes lack of appetite, poor growth, and fits or convulsions in these species. In hens it results in rapid loss of weight and in poor egg production and low hatchability of the eggs. Young pigs fed a ration lacking pyridoxine have little appetite, fail to grow, often have a type of anemia, and also may have fits. In rats a lack causes a characteristic skin disease.

Pyridoxine is apparently necessary for the formation of enzymes that are needed for the utilization of amino acids, and it also seems to be concerned with the formation of the hemoglobin of the blood.

Pyridoxine is very widely distributed in feeds of plant and animal origin, and it keeps well in storage. The cereal grains and other seeds and their by-products, and also milk, meat, fish, and cane molasses are good sources. Yeast and rice polish are especially rich in the vitamin.

Like other B-complex vitamins, pyridoxine is synthesized in the bacterial action taking place in the rumen of ruminants. Cattle and sheep are therefore not ordinarily dependent on a supply in their feed. However, it was found in Michigan studies that under certain conditions dairy cattle suffered from a peculiar disease, called poikilocytosis, which was apparently caused by a deficiency of pyridoxine, because of a lack of normal bacterial action in the rumen.[34] The condition was found chiefly in calves fed restricted rations or in older animals with an experimental rumen fistula (an artificial opening into the rumen). The trouble could be corrected by feeding pure pyridoxine or else yeast, which is rich in the vitamin.

216. Biotin.—Biotin, which was formerly called vitamin H, is a B-complex vitamin that is required by poultry, dogs, rabbits, monkeys, and probably some other species. Certain characteristic symptoms of deficiency are produced in these animals by feeding restricted rations very low in biotin. Much smaller amounts of the vitamin are needed than of most of the other vitamins, and it seems to be widely distributed in ordinary feeds. So far as is known, a deficiency of biotin does not occur in practical rations that are otherwise satisfactory for farm animals. In addition, biotin is synthesized in the rumen of ruminants, and also to some extent in the digestive tract of other animals.

In chicks a deficiency of biotin in restricted experimental rations produces symptoms somewhat like those resulting from a deficiency of pantothenic acid. Biotin is also necessary, along with manganese and choline, for the prevention of slipped tendons in chicks. In hens a lack reduces the hatchability of eggs but does not seem to decrease egg production.

Biotin deficiency can be produced in poultry and pigs by feeding too large amounts of uncooked eggs, such as waste eggs that fail to hatch in the incubator. This is because uncooked egg white contains a compound called avidin, that makes biotin unavailable. (976)

The biotin content has not been determined in many feeds, but apparently it is present in sufficient amounts in most feeds. Alfalfa hay, green forages,

grains, soybean oil meal, cane molasses, and yeast have been found to be good sources. It is very stable in feeds.

217. Choline.—Choline, one of the B-complex vitamins, has important functions in animals. It is a part of lecithin, the phospholipid which is essential in the assimilation and transport of fat. (14, 47) A compound of choline is also concerned in the transmission of nerve impulses.

When fed usual rations, most animals are able to make sufficient choline in their body tissues from other compounds to meet their needs. Also, choline is synthesized by bacterial action in ruminants. The formation of choline in the body itself seems to depend on adequate supplies of other vitamins, especially vitamin B_{12}. Poultry are able to make less choline than the larger farm animals, and shortly after birth pigs and calves have less ability to make it.

In chicks and young turkeys a deficiency of choline causes poor growth and also slipped tendons, or perosis. In mature birds a lack lowers egg production and increases mortality. Deficiency symptoms have also been produced in very young pigs and calves fed experimental rations purposely made very deficient in choline.

Certain compounds, particularly the amino acid methionine and the compound called betaine, can partially replace choline in function. Like choline, these compounds furnish labile, or readily available, methyl groups (CH_3 groups), needed in forming choline or methionine from certain other compounds. However, methionine or betaine cannot perform all the functions of choline, and do not prevent perosis.

Except in the case of poultry, most well-balanced rations for farm animals apparently have plenty of choline. While much larger amounts of choline are required by poultry than they need of the other vitamins, the amounts of choline in ordinary feeds are also far greater. For example, solvent-process soybean oil meal per pound has 1,285 milligrams of choline, while it has only 1.9 milligrams of riboflavin. (Appendix Table Va.) The choline requirements of poultry are stated in Chapter XXXVI, and the use of choline supplements discussed.

Most feeds apparently have good to fair amounts of choline. Liver meal, brewers' dried yeast, fish meal, meat scrap, tankage, soybean oil meal, cottonseed meal, and distillers solubles are rich in it. Fair sources are most grains (except corn and the grain sorghums), wheat by-products, dairy by-products, and alfalfa hay. Various choline supplements are now produced commercially, and choline is often included in the combination B-complex supplements sold for reinforcing poultry or other rations.

218. Betaine.—Betaine is not a vitamin, but it is treated here because it can partially replace choline in the diet, as it likewise furnishes readily usable, or labile, methyl groups. (217) In the same manner betaine may reduce the need for methionine, which also supplies labile methyl groups. While betaine can thus partially replace choline or methionine in this process, called transmethylation, it cannot perform the other functions of either choline or methionine. Dehydrated alfalfa, wheat bran, and wheat middlings are good sources of betaine, and presumably legume hay supplies it. Beet molasses is especially rich in it, and still richer is a concentrate prepared from a beet molasses residue, left after the commercial production of glutamic acid.

219. Folic acid, or folacin.—Folic acid, also called folacin and pteryl-glutamic acid, is a B-complex vitamin that is necessary for certain animals. It is called folic acid because it is present in the foliage of plants, and it is thus widely distributed in forages. Oil meals are good sources, and cereal grains supply some. So far as is known, folic acid is not deficient in the usual rations fed livestock.

Symptoms of folic acid deficiency produced in chicks fed highly purified diets are slow growth, poor feathering, bleaching of feathers, and anemia. It is apparently needed for good hatchability of eggs.

Synthetic folic acid is produced commercially, and is used in the treatment of certain anemias in humans.

Definite folic acid deficiency in young pigs has only been produced, even on a highly-purified ration, by administering a sulfa drug to prevent the formation of the vitamin in the digestive tract, or by feeding a substance that destroyed folic acid or prevented its action. In an experiment in which a ration made up of ordinary feeds was fed, but which was low in protein, folic acid addition tended to increase the gain of weanling pigs, but not on a ration with ample protein.[35]

220. Vitamin B_{12}.—The recent discovery, isolation, and commercial production of vitamin B_{12} is one of the most dramatic chapters in modern nutrition research.[36] This discovery, followed shortly by the commercial production of pure vitamin B_{12}, is of untold benefit to humans afflicted with pernicious anemia. Concentrated vitamin B_{12} supplements made for livestock feeding have also found wide use in rations for poultry and pigs not on pasture.

Previous to the discovery of vitamin B_{12}, it had been known that when poultry or swine not on pasture were continuously fed a ration having no protein supplement of animal origin, nutritive deficiencies often developed. Such deficiencies occurred even though the ration had ample protein and minerals and adequate amounts of all the vitamins then known. The term *animal protein factor* was used for the unknown factor or factors supplied by supplements of animal origin, such as fish meal, fish solubles, meat scrap, tankage, and dairy by-products.

Recent experiments with chicks and young pigs have shown that a large part of the beneficial effect produced by these feeds of animal origin when added to a ration entirely from plant sources, is due to the vitamin B_{12} they contain. However, as is pointed out later, such feeds also supply certain vitamins or nutritive essentials that have not yet been identified and isolated. These are called *unidentified vitamins,* or *unidentified food factors.* (222)

Because of these unidentified factors, optimum results may not be secured when chicks or pigs are kept under restricted conditions on a ration entirely from plant sources, even when all the known vitamins, including vitamin B_{12}, are supplied.

Through fine teamwork of a group of scientists, pure vitamin B_{12} was produced commercially and made available to the medical profession within four months after the discovery was first announced. This rapid development of a process for producing the pure vitamin is especially remarkable, because of the mere traces of the vitamin there are in the sources from which it can be isolated. For example, a ton of liver, one of the richest sources, contains much less than a gram of vitamin B_{12}.

The vitamin is synthesized by several kinds of micro-organisms, including some of those that produce antibiotics. Fortunately, it can be prepared commercially from the mother liquor left after most of the antibiotic is removed in the preparation of the antibiotic product. From these sources pure crystalline vitamin B_{12} is produced for use in medicine. Also from these sources *vitamin B_{12} feed supplements* are made for use in stock feeding. The vitamin B_{12} content per pound of such supplements is guaranteed by the manufacturer. Some of the vitamin B_{12} supplements contain not only the vitamin, but also guaranteed amounts of an antibiotic. Such a supplement is termed a *vitamin B_{12} and antibiotic feed supplement.* (966)

Vitamin B_{12} is the most expensive organic product made commercially, the current price being about $300.00 per gram for the pure crystalline vitamin. Nevertheless, the quantity required in a hypodermic dose for treating pernicious anemia is so small (only 15 micrograms) that the vitamin B_{12} in the dose costs less than a cent.

The high cost of the pure vitamin per gram is not surprising, considering the fact that very complicated chemical processes are required to recover the vitamin from the mere trace in the liquor from the microbial fermentation. This commonly has only 1 to 2 grams of the vitamin per ton of liquor. The price of

the vitamin in vitamin B_{12} feed supplements is much less than for the pure crystalline vitamin, because the process of manufacture is far simpler.

Vitamin B_{12} is probably needed by most animals, but it is synthesized in plentiful amounts in the bacterial fermentation that occurs in the rumen of ruminants. A certain amount of the vitamin is also apparently produced in the intestines of other animals, but the quantity thus made available to the animal is not sufficient to meet the needs of poultry and swine. They therefore need a source in their feed.

However, only very small traces of vitamin B_{12} are needed by poultry and pigs, as shown in later chapters. For example, chicks need only 4 micrograms per pound of feed. The minute size of this requirement is shown by the fact that an ounce of the pure vitamin would be sufficient for 7 million pounds of feed.

The vitamin B_{12} requirements of poultry and swine and the use of vitamin B_{12} supplements for them are discussed in Chapters XXXVI and XXXIV.

Vitamin B_{12} contains about 4 per cent of cobalt as an essential part of the vitamin. As stated in the previous chapter, it is believed that the chief cause of cobalt-deficiency troubles in ruminants is a lack of vitamin B_{12}, because of the greatly decreased formation of the vitamin in the rumen when there is a serious lack of cobalt in the food. (**175**)

The chemical name for vitamin B_{12} is cyanocobalamin. A closely related compound, Vitamin B_{12b}, seems to be equally effective in animals.

It is believed that feeds of plant origin, even green, growing forages, contain little or no vitamin B_{12}. In spite of this, young poultry or pigs on good pasture apparently have no deficiency of the vitamin, even when fed a ration that would be lacking in it if fed in dry lot.

Appendix Table Vb states the approximate vitamin B_{12} content of various feeds, so far as data are available.

221. Other B-complex vitamins.—*Inositol* and *para-aminobenzoic acid* are other B-complex vitamins that have been identified and isolated. Both are widely distributed in common feeds, and so far as is known, a deficiency of either of these vitamins does not occur in ordinary rations fed farm animals. Apparently these vitamins are synthesized in the digestive tract or in the animal tissues.

Inositol is a part of phytic acid and phytates, complex phosphorus-containing compounds in plants. (**151**) Inositol is an essential nutrient for some kinds of yeast and fungi. By feeding highly-purified diets, it has been found that it is required by certain laboratory animals and by chicks.

Para-aminobenzoic acid, abbreviated to PABA, is a relatively simple organic compound that is a part of the folic acid molecule. It is a nutritive essential for certain bacteria and for some laboratory animals. It has also been reported that para-aminobenzoic acid increased the growth of chicks fed a highly-purified diet containing none of the vitamin.

222. Unidentified vitamins.—That certain unidentified vitamins or growth factors are required by young chicks has been shown in recent experiments in which highly-purified diets have been fed, containing all the known essential vitamins, including vitamin B_{12}. These experiments are summarized in Chapter XXXVI.

At least three unidentified vitamins seem to be required by chicks, and in addition, an unknown trace mineral or combination of minerals. One of the unidentified vitamins, called the fish soluble factor, is supplied in the largest amounts by fish solubles, fish meal, liver meal, and penicillium mycelium meal. Meat scrap has somewhat less, and there is a smaller amount in dried skimmilk, dried buttermilk, and dried whey.

A second unidentified vitamin, called the distillers solubles factor, is supplied by grain or molasses distillers solubles and brewers' dried yeast. A third, called the grass juice factor, is well supplied by fresh green forage, dried whey, dried skimmilk, and brewers' dried yeast, and is also furnished by some alfalfa meal. Soybean oil meal and also grain or molasses fermentation solu-

bles have small amounts of this factor.

Recent experiments with baby pigs fed purified diets indicate that very young pigs may require similar or the same unidentified vitamins, in addition to those which have been isolated and identified.

V. Other Vitamins

223. Vitamin E.—Vitamin E is apparently concerned with several body functions, but the processes involved in certain of these are not yet known. Vitamin E was first discovered in experiments with rats, in which it was found that sterility of both males and females was produced on a highly-purified diet. This was found to be due to a lack of a vitamin, called vitamin E.

Different forms of vitamin E have been identified, which are closely related complex organic compounds called tocopherols. These not only occur naturally in plants and in animal tissues, but they have also been synthesized chemically from other compounds. Alpha-tocopherol is believed to be the most potent of the forms of vitamin E. All are soluble in fat and fat solvents.

Reproductive failure can be caused in chickens on a ration purposely made very deficient in vitamin E, but such an effect in swine is less definite. Cattle and goats have reproduced normally on rations made very deficient in vitamin E.

In some animals a serious lack of vitamin E causes a degeneration, or dystrophy, of certain muscles, including the heart. It is shown in Chapter XXXI that the "stiff lamb disease," which sometimes occurs in young lambs, can be prevented or cured by vitamin E. A deficiency of the vitamin likewise seems to be the cause of the "white muscle disease," which sometimes causes serious losses of calves, especially in certain range districts.

In Minnesota experiments reproduction was normal when dairy cattle of both sexes were fed rations devoid of vitamin E.[37] However, after cattle had been kept on an abnormal ration, devoid of the vitamin, for consecutive years, in some cases death occurred suddenly because of heart degeneration.

In New York investigations there was no improvement in the fertility of bulls used heavily in artificial insemination when wheat germ oil, which is very rich in vitamin E, was added to an ordinary ration.[38] Goats reproduced normally during successive generations in Iowa experiments when fed rations that produced reproductive failure in rats, because of the lack of vitamin E.[39] In other Iowa studies the reproductive performance of ewes fed and managed properly was not significantly improved when additional vitamin E was supplied by feeding wheat germ oil.[40]

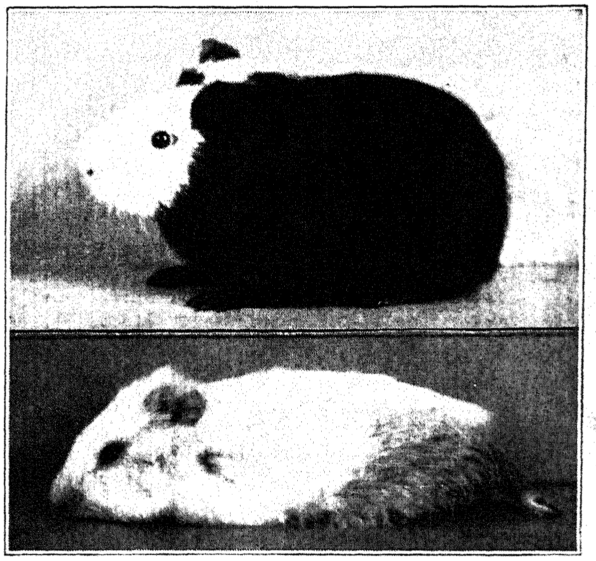
In chicks a lack of vitamin E produces the disease called nutritional encephalomalacia, or "crazy chick disease." In mature fowls a prolonged lack causes lowered hatchability of eggs and sterility of males. The exact requirements of poultry for vitamin E have not yet been determined, because most good rations seem to have adequate amounts. Further information concerning vitamin E in poultry feeding is given in Chapter XXXVI.

Vitamin E is widely distributed in livestock feeds and also in human foods that have not been too highly refined. It is abundant in the cereal grains and most other seeds, where it is present chiefly in the oil of the germ and not in the endosperm. Wheat germ oil is especially rich in vitamin E and is therefore used as a vitamin E supplement. The vitamin is also abundant in the green-leaved parts of plants and in good-quality hay, and is supplied in smaller amounts by animal tissues and eggs. Butterfat and lard have little vitamin E.

Vitamin E keeps well in ordinary feeds but is destroyed by the presence of rancid fats or other substances that favor oxidation. If concentrate mixtures are not stored too long, the vitamin E value is retained satisfactorily.

Nebraska and Minnesota experiments indicate that the usual rations fed farm animals will furnish ample amounts of vitamin E.[41] In the Nebraska studies female rats which had become infertile

on a diet deficient in vitamin E were restored to fertility when only 20 to 25 per cent of any of the following common feeds was added: Alfalfa hay, wheat bran, wheat shorts, linseed meal, hominy feed, white or yellow corn, or kafir grain. In the Minnesota experiments the following additional feeds were found to supply enough vitamin E for successful reproduction of rats, when the same proportions of these feeds were fed as are commonly used for dairy cattle: Prairie



EFFECT OF A LACK OF ASCORBIC ACID ON GUINEA PIGS

Above, a thrifty guinea pig, which received ample ascorbic acid. Below, a guinea pig suffering from scurvy, produced by a lack of the vitamin. (From Wisconsin Station.)

hay, reed canary grass hay, wheat or rye straw, oat hulls, barley grain, corn gluten meal, corn bran, dried molasses beet pulp, wheat gluten, cane molasses, meat scrap, fish meal, or blood meal.

Advertising claims have been made that the addition of wheat germ oil or other vitamin E concentrates to the usual rations for farm animals will prevent or cure sterility and be otherwise beneficial. Most nutrition authorities believe, however, that the use of vitamin E supplements for livestock is not generally beneficial, except when such a supplement is advisable to prevent one of the diseases mentioned previously. In spite of certain claims made, the addition of a vitamin E supplement to ordinary rations for dairy cows does not increase the yield of milk or raise the fat percentage.[42]

Very potent vitamin E concentrates are made commercially by extracting the small amounts in corn, cottonseed, soybean, or wheat germ oil, which contain only 0.1 to 0.3 per cent of the vitamin. Similar vitamin E supplements are made synthetically.

224. Ascorbic acid, or vitamin C.—Ascorbic acid, or vitamin C (also called the anti-scorbutic vitamin), is probably required by all species of animals. However, in most species ample amounts of the vitamin are made in the body tissues from other substances, and a supply in the food is not needed. Only human beings, monkeys, and guinea pigs lack this ability to synthesize ascorbic acid. Ordinarily, it is not necessary to give any attention to ascorbic acid in feeding farm animals.

A deficiency of ascorbic acid in man, monkeys, or guinea pigs causes scurvy. The chief symptoms of this nu-

tional disease are loosening of the teeth, inflammation of the gums, hemorrhages, brittleness of the bones, slow healing of wounds, and loss of vigor. In this country scurvy among humans has now become rare, because of the universal inclusion of fruits and vegetables in the diet, and the use of orange juice or tomato juice for young infants before they can consume other foods rich in ascorbic acid. In farm animals conditions resembling scurvy are practically unknown.

Dairy cows in South Dakota experiments had a normal content of ascorbic acid in their blood after being confined to the barn for 3 or 4 years and fed a ration having practically none of the vitamin.[43] This shows that they were able to synthesize sufficient amounts in their bodies.

Fresh fruits, vegetables, and green forages supply ascorbic acid, the content in citrus fruits, tomatoes, spinach, cabbage, and peppers being especially high. The vitamin is destroyed by oxidation in the heating of foods in the presence of air and in the drying of forage. Mature seeds and their by-products, and also hay and other dry forage, have no vitamin C. Silage may contain appreciable amounts. The vitamin is formed during the germination of seeds, and therefore sprouted seeds are rich in it.

Some of the ascorbic acid in foods is in a partially oxidized form, called dehydro-ascorbic acid. This is equal in potency to the common form, but it is readily oxidized further to inactive compounds. Ascorbic acid is soluble in water, which fact increases the loss of the vitamin in cooking by boiling, if the cooking water is thrown away.

It was suggested from studies some years ago that in some cases cattle might not form enough ascorbic acid in the body to meet their needs, and that this might be the cause of sterility in cows and bulls.[44] Although the hypodermic injection of a solution of ascorbic acid was apparently the cause of restored fertility in some instances, such results have not been secured in later tests.

Feeding ascorbic acid to ruminants does not increase the content in the body, because it is destroyed, or mostly destroyed, by the fermentations in the rumen. However, the formation of ascorbic acid in the body tissues can be increased by feeding doses of a drug called chlorobutanol.

In a recent Wisconsin experiment neither the hypodermic injection of ascorbic acid nor the feeding of chlorobutanol significantly increased the conception rate in hard-to-settle cows.[45] In a study by the United States Department of Agriculture the hypodermic injection of ascorbic acid in bulls suffering from vitamin A deficiency did not restore sexual activity or improve the potency of the semen.[46]

225. Vitamin K.—Vitamin K, the anti-hemorrhagic vitamin, is necessary, at least in some species of animals, to preserve the clotting power of the blood. If chicks are fed restricted experimental rations deficient in vitamin K, the blood will lose its power to clot and serious hemorrhages will result from slight wounds or bruises. The blood fails to clot because the vitamin deficiency results in a decrease of the prothrombin content in the blood. Prothrombin is the substance from which the enzyme is formed that clots blood when it is shed.

Fortunately, in ruminants ample vitamin K is synthesized by the bacteria in the rumen, and thus made available to the animal. The vitamin is also produced by bacteria in the intestinal tract of most animals. With the exception of poultry, in whose short intestinal tract less formation of vitamin K apparently occurs, livestock are not dependent on a supply of the vitamin in their food.

While symptoms of vitamin K deficiency are readily produced in chicks on restricted rations lacking the vitamin, symptoms of deficiency are not produced in hens fed the same ration. This is apparently because more of the vitamin is made in the intestine of the older birds. A lack of vitamin K in the ration of hens does, however, result in such a low content of the vitamin in their eggs that chicks hatched from the eggs may

bleed seriously from minor wounds, such as wing banding.

Ample amounts of vitamin K are widely distributed in green, leafy forages, either fresh or dried. Other sources are fish meal, liver, and soybeans. Since vitamin K is a fat-soluble vitamin, solvent-process soybean oil meal has little. Vitamin K has good stability in feeds.

There are several forms of vitamin K, and a synthetic compound, menadione, is produced commercially, which has an even greater anti-hemorrhagic potency than vitamin K.

Only 1 to 2 per cent of alfalfa meal of good quality usually supplies plenty of vitamin K in poultry rations, even for chicks. Recent experiments show that the requirement of poultry for the vitamin is considerably increased if there is added to the ration a high level of certain drugs, such as sulfaquinoxaline (for coccidiosis control) or arsonic acid derivatives (as a growth stimulant).[47] Hemorrhagic trouble may then occur in chicks on a ration that would be otherwise satisfactory. This can be prevented by increasing the percentage of alfalfa meal, or by adding to the ration a vitamin K supplement, such as menadione.

It has recently been reported that the addition of menadione to the concentrate mixture for dairy cows reduced the tendency for oxidized flavor to develop in milk.[48]

While vitamin K is not ordinarily of importance in the feeding of farm animals, except chicks, it is of much value in human surgery and medicine. For example, it is effective in preventing undue bleeding in certain operations and in treating hemorrhagic diseases of newborn infants.

226. Vitamin interrelationships.— Recent investigations, especially with chicks, have shown that the amounts of certain vitamins needed may be affected by the supply of another vitamin or of some other nutritive essential. The fact that niacin can be formed in the body from the amino acid tryptophan has already been mentioned. (213) Thus a liberal supply of tryptophan reduces the amount of niacin needed in the food.

It has also been shown previously that part of the functions of choline can be performed by betaine or by methionine. (217) Both these, like choline, furnish labile, or readily available, methyl groups necessary in certain syntheses in the body.

In chicks, the requirement for choline is reduced when ample vitamin B_{12} and folic acid are supplied, as these vitamins are concerned in the synthesis of methyl groups in the body. A high level of fat in the ration increases the need for choline, since choline is a part of lecithin, a phospholipid which is involved in the transport of fat in the body.

It has been shown in the preceding chapter that the requirement for vitamin D is increased if a ration has insufficient phosphorus or calcium, or if there is an improper proportion or ratio between the amounts of calcium and phosphorus.

In some experiments the addition of an effective antibiotic feed supplement to a ration for chicks has seemed to reduce the need for certain B-complex vitamins. On the other hand, the requirement for vitamin K is greatly increased by the continuous high-level feeding of certain drugs. (225)

Such relationships as these show how a lack or even an excess of one nutritive essential may affect the need for another nutrient.

QUESTIONS

1. Define *vitamin.*
2. Of what importance are green forage crops, including pasture, in meeting the vitamin requirements of farm animals?
3. What are the best substitutes for green forage crops in this respect?
4. Discuss vitamin A briefly, stating: (a) Its importance for farm animals; (b) its functions and the effects of a deficiency.
5. Explain the relationship between carotene and vitamin A.
6. Define a U.S.P. Unit of vitamin-A value.
7. Discuss the losses of carotene and vitamin A in feeds.
8. Are the following roughages rich, me-

dium, or poor in carotene content: (a) Actively-growing pasture plants; (b) mature, weathered forage; (c) green, leafy alfalfa hay; (d) corn silage; (e) alfalfa silage?

9. What is the relative carotene content of the following: (a) Yellow corn; (b) white corn; (c) barley, oats, wheat, or grain sorghums; (d) corn gluten feed from yellow corn; (e) ripe peas of green varieties; (f) soybeans; (g) carrots; (h) sweet potatoes; (i) potatoes; (j) whole milk; (k) skimmilk; (l) egg yolk; (m) tankage or meat scrap?
10. Should special concentrated vitamin-A supplements ordinarily be used for dairy cows, beef cattle, sheep, or horses?
11. Discuss the functions and importance of vitamin D.
12. What are the effects of a deficiency of vitamin D on: (a) Young animals; (b) pregnant animals; (c) mature fowls?
13. Explain the relation of light to vitamin D.
14. Of what importance is sunlight in meeting the vitamin D needs of farm animals?
15. What is the relative value of vitamin D_2 and vitamin D_3 for poultry?
16. What is the form of vitamin D in: (a) Field-cured hay; (b) irradiated yeast; (c) fish-liver oils?
17. Discuss the stability of vitamin D.
18. What is the relative vitamin D content of the following: (a) Field-cured alfalfa hay of good quality; (b) green, growing plants; (c) hay-crop silage; (d) cereal grains and by-products; (e) fish meal; (f) meat scrap or tankage?
19. What concentrated vitamin D supplements are used for poultry; for 4-footed animals?
20. What is vitamin-D milk and how is it produced?
21. Why are the B-complex vitamins not generally important in feeding cattle or sheep?
22. When might it be economical to add yeast to a ration?
23. What are the effects of a deficiency of thiamine? Is thiamine necessary in stock feeding?
24. Of what importance is riboflavin in stock feeding? What feeds are rich in riboflavin?
25. Discuss the importance of nicotinic acid in stock feeding. Name 5 feeds that are good sources of this vitamin and 4 that are rather low in it.
26. Of what importance are the following in feeding farm animals: (a) Pantothenic acid; (b) pyridoxine; (c) biotin; (d) choline; (e) folic acid?
27. Discuss the use of vitamin B_{12} feed supplements for livestock.
28. Discuss the importance of vitamin E for farm animals.
29. For what animals is ascorbic acid important? What feeds are rich in it?
30. What is the function of vitamin K? Is it important in feeding most farm animals?

CHAPTER VIII

MAINTAINING FARM ANIMALS

I. Requirements for Heat and Energy

227. Maintenance needs of animals.—On the average, fully one-half the feed eaten by farm animals is used merely to maintain the necessary life processes. Only the remainder of the food can be converted into such useful products as meat, milk, eggs, work, or wool. It is therefore highly important to understand the maintenance requirements of animals.

The amount of food that is needed merely to support an animal when doing no work and when yielding no product, is called a *maintenance ration*. When an animal receives a maintenance ration, its body will neither gain nor lose in protein, fat, or mineral matter.

To maintain an animal at rest without losing or gaining in weight, it must have adequate supplies of the following: (1) Heat to maintain the body temperature; (2) energy to carry on the vital functions, such as breathing; (3) protein to repair the small daily waste of protein tissues; (4) mineral matter to replace the small but continuous loss of minerals; (5) vitamins; (6) water; and (7) air. In addition to these nutrients, the requirements for which are discussed in this chapter, it has been shown in Chapter V that at least young calves, lambs, pigs, and chicks need a very small amount of fat or of certain fatty acids for health. (133)

228. Maintaining the body temperature.—The average body temperature of the larger farm animals is not far from 100° F., differing somewhat with the various species of animals and also slightly with individual animals of the same species. Since the body temperature of warm-blooded animals is higher than the air temperature, except on the hottest summer days, it is evident that heat must normally be produced in their bodies to keep them warm.

Heat is produced by all the oxidations which take place in the body, no matter whether of food yet in the digestive tract, or of nutrients in the muscles and other tissues of the body. In the case of animals exercising normally, the greater part of the heat is produced in the muscles, since all muscular contraction is caused by the oxidation of nutrients in the muscles. Even when the muscles are not actively contracting, they are in a state of some tension, and a certain amount of heat is being produced in them.

It has been shown in Chapter III that considerable heat is produced, especially in the case of ruminants, in the fermentations of carbohydrates that occur in the digestive tract. Also, all the energy that is used up in the digestion and assimilation of food and in other forms of internal work is finally changed to heat. (68) Though this energy is lost so far as useful production is concerned, the resulting heat helps to maintain the body temperature. Even with such an easily digested feed as corn, about one-third of the total energy in the digested nutrients is unavoidably converted into heat in this "heat increment," or so-called "work of digestion." With roughages, such as hay and straw, the proportion of energy that is thus converted into heat is much larger.

Unlike the burning of fuel in a stove, the oxidations in the body take place at a comparatively low temperature. In still another respect, the body oxidations differ radically from ordinary burning of fuel. In a furnace the wider the draft is opened, increasing the supply of oxygen, the more rapid will be the combustion. However, in the body, so

long as there is a normal supply of oxygen, the rate of burning of the food nutrients is independent of the supply of air. Hence, the greater intake of oxygen in unusually deep breathing will not in itself cause an increase in heat production, though the increased muscular work in such breathing may lead to a slight increase in the production of heat.

229. Normal body temperatures of different farm animals.—The normal temperature of different animals of the same species may vary considerably. On the other hand, the temperature of an individual animal, if healthy, varies only within a narrow limit, a departure of even one degree from normal with farm animals generally indicating some bodily derangement.

The normal body temperatures of various farm animals are as follows: [1] For dairy cows the range is 100.4—102.8° F. (38.0—39.3° C.) and the average is about 101.5° F. (38.6° C.). For beef cows the range is 98.0—102.4° F. (36.7—39.1° C.) and the average is about 101.0° F. (38.3° C.). For sheep the range is 100.9—103.8° F. (38.3—39.9° C.) and the average 102.3° F. (39.1° C.). For horses the range is 99.0—100.8° F. (37.2—38.2° C.) and the average about 99.8° F. (37.7° C.). For swine the range is 101.6—103.6° F. (38.7—39.8° C.) and the average about 102.5° F. (39.2° C.). Chickens have a distinctly higher body temperature, with a range of 105.0—109.4° F. (40.6—43.0° C.) and an average of 107.1° F. (41.7° C.) during the daytime.

230. Regulation of body temperature.—Not only must heat be continuously produced in the body, but the temperature must be kept constant under varying external conditions and with supplies of food that differ in heat-producing power. This is done by the unconscious regulation of both the loss and the production of heat.

Extensive studies are being conducted by various laboratories, especially by Brody and associates at the Missouri Station in cooperation with the United States Department of Agriculture, on the effects of air temperature, of humidity, and of air movement and other factors on heat production and control of body temperature in farm animals.[2] Other studies on these subjects are being carried on by the United States Department of Agriculture at Beltsville, Maryland, by the California, Louisiana, and Texas experiment stations, and by scientists in India and some other tropical and semi-tropical countries.[3] Thus far, most of these investigations have been with cattle, which suffer greatly in too hot weather.

Except in very hot weather, the most important means of regulating the loss of heat is by varying the circulation of blood near the surface of the body. When the body temperature rises, more blood flows to the capillaries of the skin, where some of the heat passes off into the air. It is this which causes the flushing of the skin when one becomes heated.

If this means of control is not sufficient to keep the body temperature normal, sweat is produced in the case of animals that can sweat appreciably. If the animal has only a few sweat glands or if these are not well developed, it will begin to breathe more rapidly or to pant. This increases the loss of heat by vaporizing water from the lungs and mouth. The respiratory surface, mostly in the lungs, is far larger than the external body surface, and it is all moist, so water can be evaporated from it. In man, the respiratory surface is said to be at least 30 times the external body surface.

Unless the air temperature is as high as the body temperature, more rapid breathing also increases the loss of heat by warming the air breathed in and out.

Even in the case of animals that do not produce visible sweat, a considerable part of the heat loss is through the evaporation of water from the surface of the body in the form of insensible perspiration, in which there is no visible sweat on the skin. This is an important means of controlling the body temperature in cattle, in which the sweat glands are poorly developed, except on the nose. In Illinois tests, even at an air temperature of 69° F., as much as 40 to 50 per cent of the total loss of heat from the body was by vaporization of water (including the loss both from the skin

and from the lungs).[4] At higher temperatures the loss of heat by these means was still greater.

In the Missouri studies, the loss of heat by cattle in insensible perspiration was small at comfortable air temperatures, but amounted to as much as 70 per cent of the total heat dissipated at an air temperature of 95° F.

Animals use other means of heat control in hot weather. If it is available, they will seek shade, where it is cooler. A pig will try to keep cool by wallowing in water or mud, in order to increase the heat loss by wetting the skin. Also, a pig may burrow into cool earth.

In addition to these means of regulating the body temperature, the clothing of man, and in other animals the hair, wool, feathers, thick skin, or blanket of fat under the skin check and control the loss of heat from the body. For example, a bird can check the loss of heat in cold weather by ruffling up its feathers. Similarly, the loss of heat in an animal may be checked by the hair being more erect when it is cold. Also, when an animal is sleeping, it will tend to curl up if it is cold and to stretch out when it is hot, thus decreasing or increasing the amount of body surface exposed.

231. Controlling the production of heat in the body.—When the temperature of the air is too cold, then the production of heat in the body must be speeded up. This is done by increasing the oxidations in the muscles and other tissues. On cold days animals eat more heartily and take more exercise than in warm weather, both of which result in the production of more heat. A low air temperature may also cause an involuntary stimulation of the oxidations going on in the muscles, which may even become visible in the shivering of the chilled animal. The shivering is caused by the muscular contractions that occur involuntarily in order to produce more heat.

The temperature of the air below which the oxidations in the body must be increased to keep an animal warm is called the *critical temperature* for that animal. The exact temperature will depend on the species of animal; on its coat of hair, wool, or feathers; on its degree of fatness; and, especially, on how liberally it is being fed.

The critical temperatures for farm animals with winter coats and which are fed maintenance rations are probably somewhat below 60° F. For fasting animals with normal coats the critical temperatures usually range between 60° and 70° F.[5] In the case of a man wearing ordinary clothing the critical temperature is about 49° F., and for swine it has ranged from only 52° F. or less, to 68° F.[6]

In the case of liberally-fed dairy cows or full-fed fattening animals, much heat is unavoidably produced in the mastication, digestion, and assimilation of the large rations. Except in unusually cold weather, the heat thus formed is sufficient to keep them warm, and they are not benefited by warm quarters. In such animals the critical temperature is very low.

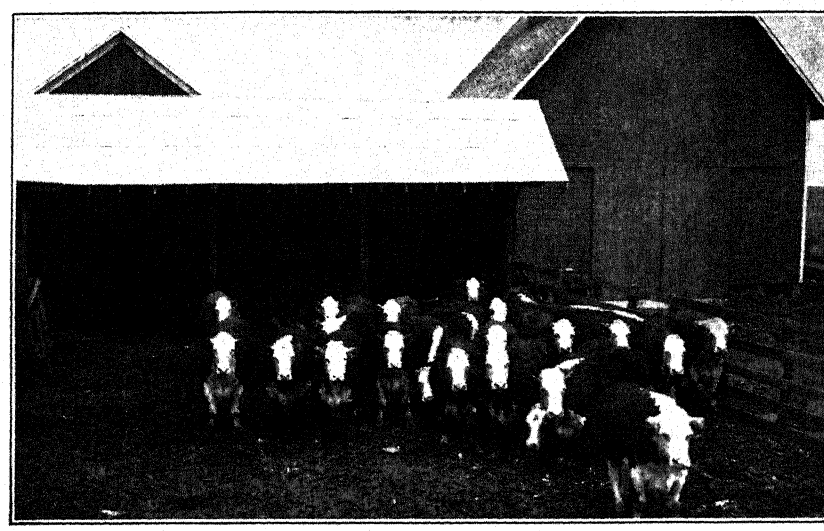
Any external conditions that increase or decrease the loss of heat from the body affect the critical temperature. For example, wind striking the body continuously removes the layer of partially-warmed air next to the skin, and thus increases the loss of heat. Therefore a cold temperature is felt much more on a windy day, and wind makes hot weather less uncomfortable. Moistness of the air increases the conducting power of the hair, wool, or clothing, and therefore animals feel the effects of damp, cold weather much more than of dry cold.

Above the critical air temperature for an animal, the rate of metabolism remains rather constant with a rise in air temperature, until the air becomes so hot that the body temperature increases. This then causes greater heat production through speeding up metabolism, in spite of the animal already being too hot. If the animal suffers so much from heat that appetite fails, then less heat may be produced, because of the decrease in heat increment. (68)

232. Shelter needed by farm animals.—The requirements of each class

of farm animals for shelter are discussed in the respective chapters of Part III. For the reason just stated, warm stables are not needed for well-fed dairy cows. Similarly, cattle and sheep fattened during the winter in cold climates will make as economical gains when housed in an open shed as in a warmer stable.

In the case of animals that are fed less liberally, feed may be saved by providing more shelter from the cold. Very young animals need warmer quarters in cold weather than older ones, because the temperature regulating mechanism is not yet well developed in the body. Thus, brooders are needed for young chicks raised artificially. Pig brooders are beneficial to young pigs in cold weather. Very young dairy calves should also have reasonably warm quarters.



FATTENING STOCK DO NOT NEED WARM SHELTER

Heavily-fed fattening steers need no winter shelter except an open shed, for an abundance of heat is unavoidably produced in the digestion of their liberal rations. On the other hand, animals being carried through the winter on scanty rations may require less feed in warmer quarters.

233. Effect of hot weather.—In very hot weather the body temperature may rise considerably, in spite of all the efforts to keep it normal. In other words, the animal will have a fever, because of the excessive heat.

Under such conditions the milk yield of cows of our dairy breeds is reduced considerably, and growing or fattening animals make less rapid gains. If the animals are subjected to very hot weather for a long period, their health may even be affected. Brody well summarizes the importance of the effect of hot weather as follows: "The serious agricultural problem in most parts of this country is not how to keep adult farm animals warm in winter, but how to keep them cool in summer."[7]

Much can be done to keep animals more comfortable and thus maintain satisfactory production in hot weather. Shade should be provided for stock on pasture, because an animal may absorb much more heat from the direct rays of the sun than is produced in the body itself.[8]

In hot climates, if there are no shade trees in pastures, portable or other shades should be made. Experiments in the hot Imperial Valley of California showed that the roof of a shade for cattle should be about 10 to 12 feet from the ground, in order to allow good move-

ment of air.[9] The roof should be of insulating material, like hay, or of reflecting material, like aluminum. The shade should be large enough to accommodate the animals without crowding together, as this lessens heat loss from their bodies.

In these California studies, with an average air temperature of 91.8° F., fattening cattle provided with cooled drinking water (65° F.) gained 0.26 to 0.44 lb. more a day than others getting uncooled water (89° F.).

much more heat and absorbs less than does long, wooly hair, such as our beef breeds tend to have. Such a coat is a benefit in cold weather but a detriment in heat.

In hot weather animals are more comfortable on a green, growing pasture than in a bare paddock.[11] This is because the air temperature near the ground in the pasture is appreciably lower, due to the evaporation of water from the growing plants. When the weather is hot, stock on pasture graze much less than normal during the heat of the day and less total time in the 24 hours.[12] They will therefore not get their fill unless there is an abundance of palatable forage.

SHADE SHOULD BE PROVIDED IN HOT WEATHER

In hot weather stock on pasture should be provided with shade. Where there are no shade trees in the pasture lot, a cheap movable shelter will furnish shade.

Anything that restricts good air movement is detrimental to stock in hot weather. Wire-fence corrals are therefore preferable to small, heavy wooden corrals. The latter not only hinder free air movement, but also reflect and radiate heat.

The absorption of heat from sunlight is decidedly less in the case of animals with light-colored coats than by those with dark coats.[10] This is because more of the rays are reflected from the light-colored coat. It is of interest to note that most of the native breeds of cattle in tropical countries have light-colored coats, usually gray or light fawn-colored. A dense, short, glossy hair coat reflects

In very hot weather swine, which have poor ability to get rid of excess heat, suffer much less if they can wallow in water. This should be provided in a concrete wallow, or a portable metal wallow, which can be kept sanitary, and not by a filthy mud hole. Another method of letting swine get their skin wet is to let water trickle over a clean concrete floor in a hog pen.

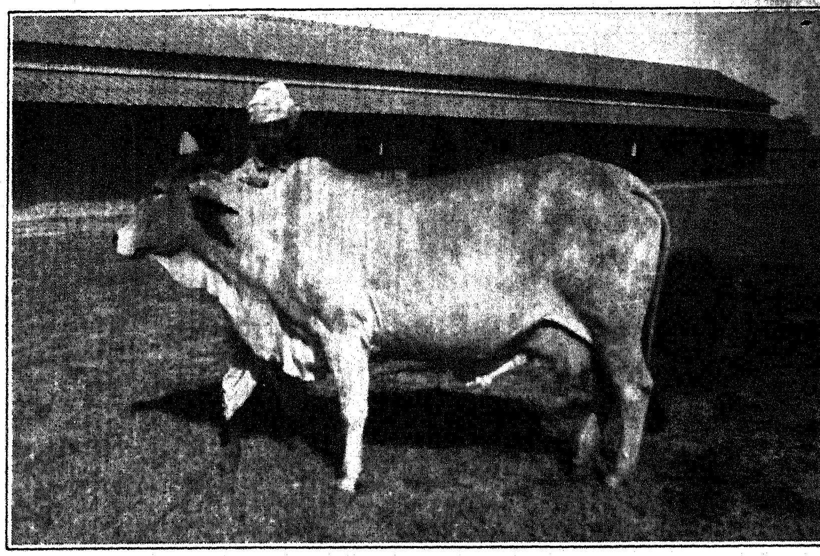
Experiments have been conducted

to find whether an automatic sprinkling device that produces a very fine spray would increase the milk yield of dairy cows in hot weather. The results thus far reported have not been encouraging.[13]

Animals can stand much hotter weather in a dry climate than where the humidity is high. This is because the animal can get rid of less heat by the evaporation of water when the air is moist. The effect of high humidity is much less in the case of cattle than for animals that can sweat freely.[14]

234. Heat tolerance of various farm animals.—The various kinds and breeds of livestock differ greatly in their ability to endure hot weather. The breeds and breeding of farm animals are outside the scope of this volume, and therefore only certain general statements concerning this matter are made here.

The European breeds of cattle do not thrive under tropical conditions where Zebu cattle (also called Brahman, Indian, or Pakistani cattle) do well. Afrikander cattle also tolerate heat. In some tropical countries the native cattle, developed over hundreds of years in the hot climate, stand the climate well, but they are nearly all low producers of milk or beef.



ZEBU CATTLE CAN ENDURE EXTREMELY HOT WEATHER

Zebu cattle tolerate very hot weather much better than cattle of the European breeds. This may be partly due to a more extensive development of sweat glands. This Zebu cow was the highest producer in the dairy herd at the Karnal Breeding Station in India at the time of a visit there by the author. She yielded 7,000 lbs. of milk in her first lactation and over 10,000 lbs. in her second.

Among the European breeds, Brown Swiss and Jerseys tolerate heat much better than Holsteins, Ayrshires, Herefords, Aberdeen-Angus, or Shorthorns. In the Missouri studies with cows, the marked increase in body temperature and the decline in feed consumption and milk production with increasing air temperature, began at about 70° F. with Holsteins, 75° with Jerseys, 80° with Brown Swiss, and 90 to 95° with Brahmans.

Because the infusion of Zebu blood greatly increases the tolerance to heat, cross breeding with Zebus is widely practiced in tropical and semi-tropical regions. Such cross breeding is common in commercial beef herds in Florida and in the Gulf Coast district of this country

where the summers are hot and humid.

From surveys the author has made of livestock production in Venezuela and the Philippines, he is convinced that beef production can be greatly increased in such regions by introducing Brahman or other Zebu blood into the native cattle.

In order to combine the superior beef-producing ability of the European beef breeds with the heat tolerance of Zebus, the Santa Gertrudis breed was developed by the King Ranch of Texas, combining the blood of Shorthorns and of Brahmans.[15] Other cross-bred breeds being developed are the Brangus, the Braford, the Charbra, and the Beefmaster.

It is more difficult to develop high-producing dairy cattle suited to very hot regions, because most of the Zebu breeds are low producers of milk. Among such breeds that have fair milk-producing ability are the Red Sindhi, a breed of very small cattle, and the Tharparker and Sahiwal breeds.

Experiments are being conducted by the United States Department of Agriculture and some of the southern experiment stations in which the blood of Red Sindhis is being combined with that of Jerseys and other European breeds. Similar breeding investigations are being carried on in Jamaica and in other tropical regions.

Part of the greater ability of Zebu or Brahman cattle to endure heat is undoubtedly due to the fact that they have a larger skin area per 100 lbs. of weight than do the European breeds. This is because of the pendulous dewlap and navel fold, the long ears, and the hump. The greater surface area is a decided benefit to them in hot weather, but it is a disadvantage in very cold weather, as it increases the heat loss from the body.

In the Missouri studies, the Brahman cows had a lower rate of metabolism and consequently of heat production than cows of European breeds. This was partly, but not entirely, due to their much lower milk production. Contrary to some opinions, the Brahman cattle did not sweat visibly at high air temperatures. Nevertheless, they were able to get rid of more heat by evaporative especially at high humidity, t cattle of European breeds.

In bringing animals into a h mate from a cooler region, they should reach the hot district at a cooler part of the year, so they can gradually become accustomed to the heat. In cattle the heat tolerance is lowest for calves, and it increases gradually up to about 4 years of age.

Water buffaloes can endure heat and humidity well, if they can immerse themselves in water or mud each day, or if their coats are wet, by splashing water on them. This is in spite of the fact that they are dark in color. Horses stand tropical climates better than the European breeds of cattle, and mules and donkeys have even greater heat tolerance.

The author was surprised to find in a survey he made of the livestock industry of the Philippine Islands that the improved breeds of swine get along much better than European breeds of cattle under tropical conditions, if they are provided with water wallows and strict attention is given to sanitation.

235. Energy required for vital functions.—In a maintenance ration a certain amount of net energy must be supplied for the various activities of the body when it is idle. Even when an animal is not eating food or assimilating a meal, energy is required for the work of the heart, lungs, and other internal organs. Also, nutrients are constantly being oxidized in the muscles to keep them in a state of tension. In the case of most animals more nutrients must be oxidized when they are standing than when they are lying at rest, as the muscles are under greater tension. If an animal moves about, a still larger amount of energy is needed for the movements.

The amount of energy needed for all these purposes is relatively small, however, for an animal that is being maintained at rest in a stall. The greater part of the food is required merely as fuel to keep up the body temperature. For example, to maintain a horse at rest only one-third of the total energy of the

t·..ion need be supplied in the form of net energy, the remainder being used solely to warm the body.

Maintenance rations for livestock, except swine and poultry, may therefore consist largely of roughages, such as hay and straw, which furnish abundant heat, but which do not yield a large amount of net energy. Since the ration must furnish at least a minimum amount of net energy, animals cannot be maintained without loss of weight on such a feed as wheat straw alone, which furnishes no net energy to horses and but little to ruminants.

236. Total digestible nutrients required for maintenance.—Numerous studies have been made of the amounts of total digestible nutrients or of energy required for the maintenance of farm animals. One method of conducting such experiments is to find the minimum amount of a suitable ration that will actually maintain the animal over long periods in a thrifty condition, without loss of weight. In such experiments care must be taken that the ration contains adequate supplies of protein, minerals, and vitamins.

Unless such investigations are continued for long periods, the results may not be accurate. The animal may not lose weight, even when there is some loss of protein or fat, because there may be a compensating increase in the water content of the body. However, when such experiments are conducted for many months and with a sufficiently large number of animals, they provide the most reliable data concerning the actual amounts of nutrients required for proper maintenance.

The most extensive of such studies are those of Hills and associates, who conducted investigations on the maintenance requirements of dairy cows at the Vermont Station over a period of 13 years. These studies showed that a ration having 6.48 lbs. of total digestible nutrients was sufficient for the maintenance of a 1,000-lb., dry, non-pregnant cow. It has been shown previously that a liberal ration is not digested and utilized quite so completely as a scanty ration. (101) For this reason a well-fed cow in milk undoubtedly needs more feed for mere maintenance than if she were fed a scanty ration which would maintain her weight when dry.

The available information concerning the maintenance requirements of each of the classes of stock is presented in the chapters of Part III. The Morrison feeding standards, which are given in Appendix Table III, state the amounts of nutrients that in the opinion of the author should be provided for maintaining various classes of farm animals. The standards for maintaining dairy cows and for wintering beef breeding cows, brood mares, ewes, and brood sows, provide not only enough nutrients for maintaining the mother, but also for the development of the bodies of the unborn young. (288–292)

It should be borne in mind that the amounts of nutrients recommended in these standards are not the theoretical minimum requirements, but are allowances of nutrients that should be safe under varying practical conditions. In other words, the standards provide a reasonable margin of safety to cover the considerable variations in the requirements of individual animals, in the composition of feeds, and in other conditions.

237. Basal metabolism; resting metabolism.—Another method of studying the maintenance requirements for energy is to determine in a respiration apparatus or calorimeter the amount of heat produced by an animal when at rest, and when a sufficient time has elapsed since the last meal so that there is no longer an increased production of heat due to the digestion and assimilation of food. This is called the *basal metabolism*, or the fasting metabolism, of the animal. Such determinations cannot be made until considerable time has elapsed since food has been eaten, because the heat production of the body is greatly increased while food is being assimilated. Thus, in New Hampshire experiments dry cows produced 50 to 60 per cent more heat on a maintenance ration than on the second day of fast.[16]

In determinations of the basal metabolism of humans, the experiments are made 12 to 18 hours after the last meal. In the case of farm animals, especially ruminants and

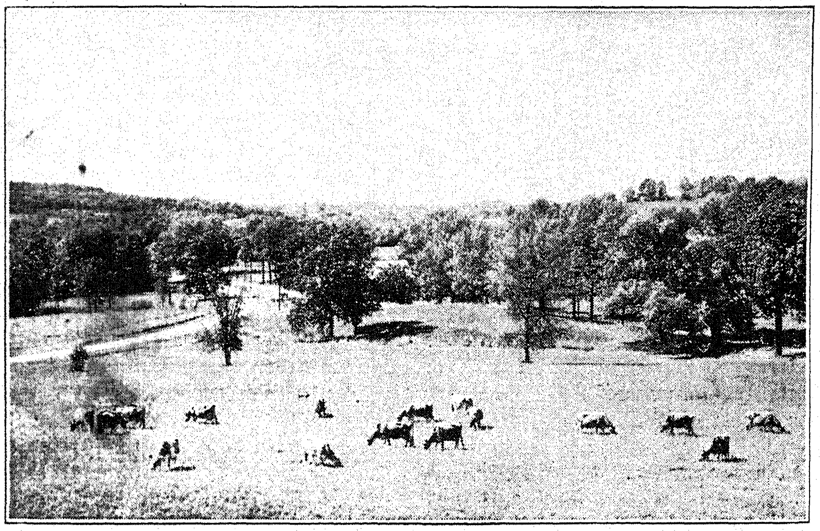
horses, a much longer period of fasting is required to reach the same state. This is because of the slow passage of feed through their digestive tracts. Therefore, what is termed the *resting metabolism* is sometimes determined, the experiments being conducted 12 hours after the last meal. This resting metabolism may be considerably higher than the theoretical basal metabolism.

The basal metabolism does not represent the total amount of nutrients or energy required for maintenance, but only the minimum amount of energy expended by the animal when at rest and consuming no food. To this amount must be added the amount used in the heat increment. Also, the amount of energy expended in the normal motions of the animal must be added to the basal metabolism.

From studies at the Missouri Station, Brody and associates have concluded that the maintenance requirements of mature animals at air temperatures above the critical temperature are about twice the basal metabolism.[17] At lower temperatures, as in the case of animals exposed to winter temperatures in the northern states, the maintenance requirements would be higher.

238. Maintenance requirements not proportional to weight.—In the older feeding standards it was assumed that the amounts of feed required for maintaining animals of the same kind but of various live weights depended on their weights. It has been found, however, that maintenance requirements are generally more nearly proportional to the amount of body surface than to the live weight. Thus, a cow weighing 1,600 lbs. does not require twice as much total digestible nutrients for maintenance as does one weighing 800 lbs. Similarly, the 800-lb. cow does not need anywhere near eight times as much nutrients for maintenance as a sheep weighing 100 lbs.

This condition is due to two factors: First, the chief loss of heat from the body is by radiation and conduction from the body surface. Therefore the loss is proportional to the amount of surface. Large bodies have less surface per pound than do smaller ones. Thus, the 1,600-lb. cow has much less body surface than two 800-lb. cows. Second, the weight of the most active tissues of the body (the internal organs, the glands, etc.) in animals of different sizes is more nearly proportional to the surface of their bodies than to their live weights.



ONE-HALF THEIR FEED IS NEEDED FOR MAINTENANCE

Even good dairy cows require for the mere maintenance of their bodies about one-half of the total feed they consume. Only the remainder can be used for milk production.

The amount of nutrients needed for the muscular work of holding the body upright and of moving about, presumably depends on the live weight. However, animals of large size may be less active than smaller ones of the same kind. This would tend to offset the difference due to weight.

From studies at the Missouri Station, Brody and associates concluded that the maintenance requirements for total digestible nutrients or energy of mature animals of various sizes are proportional to the 0.7 power of the live weight.[18] (The body surfaces of animals of various sizes are proportional to the 0.66 power of their live weights.) Kleiber of the California Station has reached similar conclusions.[19]

On the other hand, Gaines of the Illinois Station concluded from studies of the results of feeding experiments that the maintenance requirements of dairy cows were proportional directly to their live weights.[20]

The results of these various studies have been considered in the amounts of nutrients recommended for animals of various sizes in the Morrison feeding standards. The amounts of nutrients advised for maintaining dairy cows of various weights are proportional to the 0.87 power of the live weight. This factor was chosen since rations computed on this basis seemed to agree best with the methods of feeding good dairy cows that have proven satisfactory in practice.

239. Factors affecting maintenance requirements.—In feeding livestock it is important to bear in mind that any factor which decreases the digestibility or utilization of feed will increase the amount required for maintenance. Also, any condition that needlessly increases the oxidations in the body tissues will increase the maintenance requirements. Thus, a quiet animal needs less food for maintenance than a nervous, active one. This is one of the main reasons why a fattening animal that "eats and lies down" makes the most economical gains.

Exposure of animals to cold air temperatures increases the loss of heat by radiation, especially if they have scanty coats.[21] If their coats are wet by cold rain or snow, still more heat is lost, for the cold water must be warmed and evaporated by heat produced through oxidation of food. With well-fed fattening animals, the greater loss of heat through these causes may not produce any waste of food, because much more heat is being produced in the work of digesting the liberal ration than is ordinarily needed to warm the body. On the other hand, animals being carried through the winter on scanty rations have no such excess of heat, and therefore much feed may often be saved by protecting them from cold winds and storms.

As has been pointed out previously in this chapter, too high an air temperature will increase the maintenance requirements. (231)

Young animals require considerably more feed to maintain them at constant weight than mature animals of the same size or body weight.[22] This is due to a higher rate of metabolism and at least partly to their greater activity. Males of dairy cattle and swine have higher maintenance requirements than females per unit of weight, according to Missouri tests.[23] Castrated male cattle or sheep had about the same maintenance requirements as females.

Horses have higher maintenance requirements than cattle of the same weight, because they are more active. Also, the requirements are much higher for Thoroughbred horses than for draft horses, because of the great difference in temperament.[24]

It has already been mentioned that with most animals more nutrients must be oxidized when an animal is standing up than when lying down. With cattle and sheep, the increase averaged only about 9 per cent in Missouri tests.[25] Horses used no more nutrients and in some cases even less when standing than when lying down. This is perhaps the reason why many horses prefer to sleep standing up.

When an animal that has been more

liberally fed is first put on a maintenance ration, more feed may at first be required to maintain its weight than later. Apparently, after it has been on the scanty food supply for some time, it gets on a more economical basis and is able to digest and utilize its feed more efficiently. However, if an animal is unthrifty, because of semi-starvation or illness, its maintenance requirements will be higher than normal.

An animal requires more feed to maintain its live weight after it is fattened than before. This is partly because it is heavier and has a larger body surface. Also, the fat condition itself may increase the maintenance requirements per unit of weight or body surface.[26] In very cold weather, however, a blanket of fat may reduce the maintenance need, by insulating the animal against the cold.

240. Source of nutrients during starvation.—When an animal is given no food, the heat needed to warm the body, the net energy required to carry on the vital processes, and the protein and mineral matter necessary for the repair of the active tissues must all come from nutrients previously stored within the body. The small supply of glycogen in the liver and muscles is probably first used as fuel, but this is soon gone. Fat is the animal's chief reserve fuel, stored when food is abundant, against times of scarcity, and is therefore the main source of both heat and energy during starvation.

When the supply of fat begins to fail, the muscles and other protein tissues are broken down more rapidly to furnish heat and energy, and the animal finally perishes through the impairment of its organs and the lack of body fuel to carry on the functions of life. Carnivora, or flesh-eating animals, withstand hunger longer than herbivora. While dogs and cats have lived until their weights were decreased 33 to 40 per cent, horses and ruminants will die when their weight has been reduced 20 to 25 per cent.

Men have survived fasts of 30 to 75 days, and dogs have endured fasts of from 90 to 117 days without permanent ill effects. The age of the animal influences the time at which death occurs from starvation, young animals losing weight more rapidly and dying after a smaller loss of weight than old ones.

II. Requirements for Protein, Minerals, and Vitamins

241. Protein requirements for maintenance.—The heat and energy required to maintain the body can be furnished by feeding carbohydrates and fat. However, an abundant amount of these nutrients alone will not maintain an animal, for there must be a supply of protein to replace the daily break-down or wear of the protein tissues of the body. Likewise, there must be protein for the growth of the hair or wool and of the skin and hoofs, which are all composed chiefly of protein.

Because protein-rich foods are generally more expensive than those rich in carbohydrates, it is of much importance to know the minimum amount of protein needed to maintain animals in good health. Fortunately, the daily need of protein for mere body maintenance is relatively small. When ample amounts of carbohydrates and fats have been provided, dry cows and steers have been maintained on only 0.5 to 0.6 lb. of digestible protein daily per 1,000 lbs. live weight, and in some instances on even a smaller allowance.[27]

The amounts of digestible protein advised in the Morrison feeding standards for maintaining various classes of stock are based upon studies by the author of the results of feeding trials conducted by various experiment stations. Slightly larger amounts of protein are recommended than are theoretically necessary for mere maintenance. For example, 0.60 to 0.65 lb. of digestible protein is recommended for maintaining a 1,000-lb. dairy cow. It is believed that these allowances of protein will safely cover the variations in the composition of feeds that have been discussed in Chapter IV. (**95–100**) Also, this maintenance allowance will provide the relatively small additional amounts of protein needed for the development of the unborn calf until the last few weeks of pregnancy, when an additional allowance is advised.

In the opinion of the author it is

generally unwise to feed rations that supply decidedly less protein than recommended in these feeding standards. As has been explained in a previous chapter, when stock are fed rations exceedingly low in protein, the digestibility of the protein and other nutrients is often seriously decreased. (**102**) This causes a wastage of feed. In addition, a supply of protein somewhat above the minimum apparently promotes the health of animals. In well-fed animals there is a small but important reserve supply of protein in the blood and tissues. It is believed that animals with a good protein reserve are better able to resist infection, because the antibodies are produced from the serum protein of the blood.

While we generally speak of the protein requirements of animals, undoubtedly what the body really needs is not a certain amount of protein, but definite amounts of the various essential amino acids. For maintenance, the food must therefore provide not only a certain amount of protein, but also the protein must be of proper quality for the particular class of animal.

The amounts of digestible protein advised in the Morrison feeding standards are recommended on the assumption that reasonable care will be taken to provide protein of a quality that is satisfactory for the particular class of animal. The quality or kind of proteins in various feeds and rations has been discussed in detail in Chapter V.

Experiments indicate that the amounts of digestible protein required for the maintenance of animals of the same kind but of various sizes are not strictly proportional to their live weights.[28] Instead, the protein needs are proportional to the 0.7 power of the live weight, the same as in the case of the requirements for total digestible nutrients. These experiments have been taken into consideration in the amounts of digestible protein advised in the Morrison feeding standards.

242. Studying protein needs on a protein-free ration.—Some studies on the protein requirements of animals have been conducted by determining the amounts of protein lost from the body on a ration containing no protein, but which supplies an abundance of carbohydrates and fat. On such a ration, the amino acids needed for maintenance must be secured by a gradual tearing down or wasting away of the protein tissues of the body.

From such experiments and from similar investigations of others, Mitchell and associates have concluded that the 1,000-lb. animal will lose about 0.175 lb. protein daily on a protein-free ration, and that twice this amount of digestible protein in the food, or only 0.35 lb., is enough for maintenance.[29] This purely theoretical conclusion is based on the assumption that the proteins in the usual maintenance ration can be used for the repair of body tissue with an efficiency of 50 per cent. However, the author believes this is an unsafe protein allowance for maintenance, because it has not been proved in long-time feeding experiments that animals can actually be maintained in good health on such a small amount.

Other experiments have been conducted in which all food has been withheld from animals for varying lengths of time. When an animal is given no food, the nitrogen excretion (representing the loss of protein from the body) decreases rapidly at first, until the supply of amino acids in the blood and tissues, which have not yet been built into body protein, is lowered to a minimum.

The nitrogen waste in the urine then slowly decreases until it reaches a level that remains quite constant so long as heat and energy are furnished by the body fat. When the supply of the latter begins to fail, the muscles and other protein tissues must thereafter not only furnish protein for the repair of the vital body machinery, but they must also supply the necessary heat and energy. Consequently they waste more rapidly until death follows.

We might expect that when protein only is fed to a fasting animal, in an amount corresponding to the quantity lost daily during starvation, it would replace the protein wasted from the tissues, and the animal thus be brought to nitrogen equilibrium; that is, it would excrete as much, but no more, nitrogen than was contained in the food. However, when practically pure protein is fed, the loss of nitrogen can be stopped only if the supply is far in excess of the waste from the starving body. This is probably because the tissues are flooded with amino acids, the product of protein digestion, and

the wastage through deaminization is therefore greatly increased. (**51**)

When animals are fed exclusively on nitrogen-free nutrients, such as sugar, starch, or fat, the wasting away of the muscles and other protein tissues of the body is somewhat reduced, though not entirely stopped. Therefore, animals forced to live on such a diet survive longer than those wholly deprived of food. Yet, because of the continuous small waste of protein from the tissues of the body, animals nourished solely on fats and carbohydrates cannot long survive.

243. Mineral requirements for maintenance.—The necessity of an adequate supply of minerals in maintenance rations has been shown experimentally by giving animals sufficient food, but food from which the minerals have been removed as completely as possible. Even though the rations contain an abundance of protein, carbohydrates, and fat, the animals will die from mineral starvation, and generally the end will come sooner than if no food at all is given. The importance and functions of each of the necessary mineral nutrients have been discussed in Chapter VI, and further information concerning the mineral requirements of each class of stock is given in the chapters of Part III.

When an animal is merely being maintained, it is making no growth in skeleton or protein tissues, and it is yielding no product such as milk. Therefore the mineral requirements for maintenance are relatively small, particularly in comparison with those for growth or for milk production.

However, even when livestock are not being fed for production, common salt should ordinarily be supplied. Care must also be taken that the ration provides the small amounts of calcium and phosphorus needed to replace the daily losses from the body. In most regions other necessary minerals are usually furnished in sufficient amounts by the ordinary feeds.

244. Vitamins required for maintenance.—Detailed information has been presented in the preceding chapter on the functions and importance of each of the vitamins. Specific recommendations concerning the vitamin requirements of each class of stock are given in the respective chapters of Part III. Most of the vitamin investigations have been conducted to find the vitamin needs for growth, milk production, or egg production, and but little information has been secured on the maintenance requirements. It is known, however, that mature animals can be maintained in good health on decidedly smaller supplies of vitamins than are needed by growing animals or by mature animals that are producing milk or eggs. Nevertheless, to make sure that there will be no injury from a lack of vitamins, one should see that even maintenance rations provide an ample supply, especially of vitamins A and D.

245. Nutritive requirements in later life.—Very few experiments have been conducted, even with small laboratory animals, to study the nutritive requirements in later life and the effect of the diet on the length of life. Practically no information on this subject has been secured with farm animals. The limited amount of data secured with small animals indicates that the thrift and vitality of mature animals and their length of life can be definitely increased by supplying more than the bare minimum amounts of certain essential nutrients.

In extensive experiments by Sherman and associates at Columbia University, groups of rats were fed throughout life upon a ration that supported normal growth and health, with successful reproduction and rearing of young for generation after generation.[30] Other groups were fed the same, except that the proportion of milk in the diet was increased. This supplied more than the minimum amounts of high-quality protein, of calcium, of vitamin A, and of riboflavin.

The more liberal amount of milk not only increased the rate of growth and development, but also resulted in better adult vitality and appreciably extended the average length of adult life. These rats maintained the full vigor of the prime of life into the period when the other rats, fed merely a minimum diet, became definitely senile. Similar results

were secured by Orr and associates in experiments with rats in Scotland when additional milk and green food were added to a diet like that often consumed by man.[31] In further experiments by Sherman and associates it was found that the more liberal supply of calcium accounted for a large part of the improvement in the diet containing more milk.

Experiments by Henry and Kon in England and also by McCay and associates at Cornell University indicate that in later life animals are not able to use calcium as efficiently as when they are younger.[32] In the English experiments old rats steadily lost calcium from their bodies on a diet that had supplied enough of this mineral when they were younger. It was necessary to greatly increase the calcium content of the diet to get these old rats back into calcium balance. The results were similar in the New York experiments, except that in the case of old dogs it was impossible to keep them from losing some calcium from the body, even on a calcium-rich diet.

In other studies by McCay and associates on the nutritive requirements of rats during the latter half of life, it was found that a factor of great importance in determining the length of life was the degree of fatness. Rats that were not allowed to become fat outlived those that became fat.[33] Exercise was of minor importance, except as exercise reduced the tendency to lay on fat. A reasonable excess of protein over the minimum was not harmful, but too high an intake was less favorable.

III. Additional Requirements

246. Air requirements; ventilation of stables.—While animals can go without food for considerable periods, complete lack of air brings sudden death, since a continuous supply of oxygen is required for all vital processes. There is no lack of oxygen in the air of any ordinary stable, even if it is not especially ventilated. However, for other reasons an efficient ventilation system should be provided in closed stables. Proper ventilation consists of maintaining a comfortable stable temperature and a relatively low humidity of the air without drafts.[34]

We have all experienced the ill effects of poorly-ventilated rooms. These effects include depression, drowsiness, headache, and a reduced ability to do mental or physical work. It was formerly believed that the bad effects of a lack of ventilation were due to a lack of oxygen or to an accumulation of carbon dioxide, and also to a poisonous or injurious substance in the air breathed out by animals. Experiments have proved that these beliefs were untrue. Enough air enters any ordinary stable or room through crevices, etc., to prevent a lack of oxygen or an injury from too much carbon dioxide in the stable air. However, there are other reasons for providing an efficient ventilating system in stables.

A good ventilating system will make the animals more comfortable, for it will prevent the air in the stable becoming too humid, or high in moisture, due to the water vapor in the air exhaled. Also, in warm weather a ventilating system will aid in keeping the temperature of the stable comfortable, because of the circulation of air. Proper ventilation will also get rid of foul odors.

247. Other benefits of ventilation.—One of the most important benefits from proper ventilation of a stable, along with suitable insulation of the walls, is that it prevents the condensation of moisture in cold weather. In a stable without a ventilating system, water will often condense on the walls and windows to such an extent that serious rotting of the timber results. Moreover, so much water may condense in the hay mows as to cause spoilage of the hay. The coats of the animals may also become damp, causing discomfort or even disease. Because good ventilation keeps the stable much drier than otherwise, it helps prevent bacterial growth. There is thus apt to be more trouble from disease when a stable is poorly ventilated.

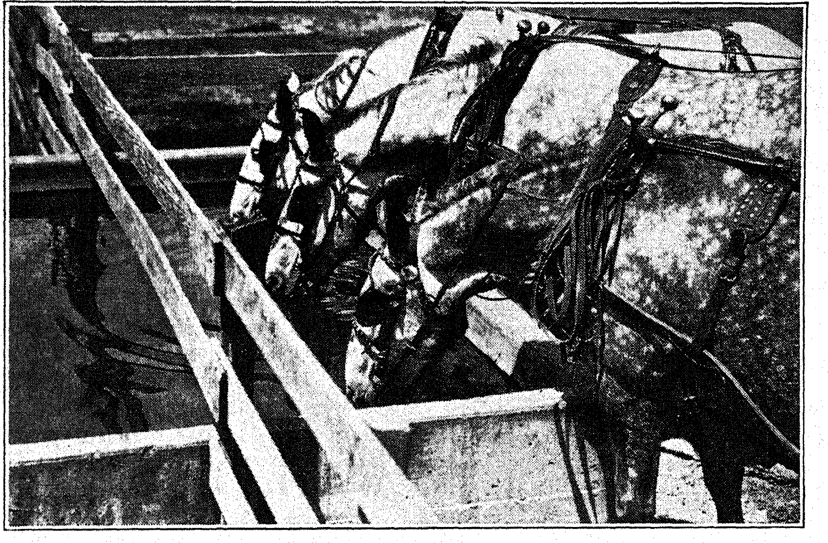
248. Water.—An abundant supply of water is needed for all the vital processes of the body, such as the digestion

and absorption of food nutrients and the removal of waste from the body. As shown previously in this chapter, water is also exceedingly important in regulating the body temperature.

Farm animals should have all the water they care to drink, for they do not take an excessive amount unless they are given salt irregularly or are forced to live on very watery foods. When water is not provided so that stock can drink whenever they are thirsty, they should be watered at regular intervals. In order to avoid disease, the water should be of safe quality. Also, if the water is not palatable, animals may not drink enough for the best results.

Animals must bring up to the body temperature all the water that they drink, thus using up heat. This does not mean that food is always wasted when cold water is warmed within the body. Animals may have an excess of heat which has been unavoidably produced in the work of digesting their food and converting the nutrients into body products or work.

However, when animals are watered only once a day, they then drink a large amount. In winter, if the water is cold, this makes a sudden demand for such a large amount of heat that food may be burned simply to warm the water, even though at other times there may be an excess of heat in the body. For this reason, feed may be saved by allowing animals exposed to cold and those fed scanty rations, to have frequent access to water, or else by warming the water. The chief advantage from heating stock-watering tanks in winter in cold climates is that it keeps them free of ice so the stock can get all the water they want at any time.[35]



FARM ANIMALS SHOULD HAVE PLENTY OF WATER

All classes of stock should have all the water they will drink. Horses doing hard work in summer need an especially liberal supply, and they are benefited by watering them at reasonably frequent intervals.

Under normal conditions animals consume a fairly uniform quantity of water for each pound of dry matter eaten. If some of the feed is succulent, such as silage, roots, or green forage, the amount of water that is drunk will be correspondingly reduced.

When entirely oxidized in the body, 100 lbs. of carbohydrates will yield 55.5 lbs. of water and 163 lbs. of car-

bon dioxide, and fats over twice as much water. The nitrogenous compounds yield a little less, because they are not entirely oxidized in the body. This shows that the animal gets some water from the dry matter of the food.

The water requirements of each class of stock are discussed in detail in Part III.

249. Saline and alkaline water.—In the drier districts water sometimes contains so much soluble mineral salts that it is unsuitable for stock. It was found in studies by the Oklahoma Station that the limit of tolerance depended on the kind of animal, the age, and the season of the year.[36] It made little difference whether the total quantity of dissolved salts was made up of a single salt or a number of salts.

It was concluded that 1.5 per cent of total salts in the water was about the safe upper limit for satisfactory maintenance. For lactating animals the limit was lower. Sheep were able to exist when the water contained 2.0 per cent or more of minerals. From Colorado studies it was concluded that even considerably lower percentages of salts in water retarded the gains of fattening animals.[37]

Animals seem to become accustomed to drinking water that is unsatisfactory at first. If good water is readily accessible, they never drink water having a harmful amount of minerals.

250. Softened water.—Claims were recently made that dairy cows produced more milk when supplied with water softened by means of a commercial water softener, than when they had hard water. However, in experiments at three experiment stations softening hard water for dairy cows did not result in any increase in milk production or have any favorable effect on the cows.[38]

251. Urinary calculi.—Sometimes male cattle and sheep, especially fattening animals, are seriously affected by the formation of urinary calculi in the bladder or kidneys. These not only cause great pain but may cause death through blocking the flow of urine, even resulting in the rupture of the bladder. The calculi are usually composed largely of mineral matter, especially phosphates or in some cases silicates. Horses or swine are rarely troubled with urinary calculi.

Several experiments have been conducted in an endeavor to find the cause of calculi and ways of preventing their occurrence.[39] However, the definite information on the subject is still very limited, because the results of the studies have been conflicting.

252. Possible causes of urinary calculi.—The trouble from calculi may be increased if animals consume an excessive amount of minerals. This may result either from mixing an undue amount of minerals in the concentrates, or from supplying a mineral mixture flavored with molasses.

The results have differed widely in trials in which the relationship of phosphorus to urinary calculi has been studied. In some experiments a low amount of calcium and a large amount of phosphorus has seemed to be a cause of calculi, and the addition of calcium carbonate has been beneficial. In certain tests the feeding of considerable wheat bran or wheat middlings, both very high in phosphorus, to fattening steers or lambs has apparently increased the trouble. However, in other experiments the addition of bone meal to a fattening ration has seemed to reduce the cases of calculi.

Insufficient water to drink may cause the trouble, as the urine is then more concentrated, and solids are more apt to separate out. Therefore, it is important that the animals have access to a convenient supply of good water. It is surprising that in one trial the rams in a lot that drank the most water had the most trouble from calculi. Salt should always be available to the animals.

There seems to be more trouble from calculi when sweet sorghum forage (either silage or dry fodder) is fed than on other rations, and also when the grain is grain sorghum, instead of corn. In certain trials sugar beet tops or beet top silage has increased calculi. **(643)** Feeding enough alfalfa hay in addition to sorghum forage or beet tops, has

seemed to reduce the trouble. A possible reason why sweet sorghum forage may increase cases of calculi is that it is high in silicates.

Rations seriously deficient in vitamin A apparently tend to produce calculi, although opinions differ as to whether a lack of vitamin A is a common cause of the trouble. The formation of calculi seems to be prevented by good-quality alfalfa hay and especially by the combination of alfalfa hay and yellow corn, both of which supply vitamin A value.

253. Feeding concentrates alone to stock.—It would ordinarily be very uneconomical to feed cattle, sheep, or horses on nothing but grain and other concentrates, because concentrates are usually much more expensive than roughages. Still more important is the fact that good roughages, such as pasturage, well-cured hay, and silage, are exceedingly important as sources of vitamins and minerals.

As a matter of scientific interest, numerous experiments have been conducted to find whether various farm animals can live on concentrates alone.[40] When cattle or sheep are fed concentrates alone, without any roughage, rumination usually ceases or is greatly decreased.

Except for a tendency to bloat, cattle and sheep may get along fairly well on concentrates alone for several months, if care is taken to provide sufficient amounts of minerals and of vitamin A and vitamin D. However, when such a ration is long continued, nutritive deficiencies usually develop, probably caused by a lack of dietary essentials that have not yet been discovered.

Many attempts have been made to raise calves on milk alone or on milk and concentrates.[41] The earlier tests usually soon ended in failure, for they were conducted before the importance of minerals and vitamins was well understood. Later trials have been successful over a longer period, when great care has been taken to add mineral and vitamin supplements to the ration. Even in these, the animals have finally developed severe nutritive deficiencies, resulting in death.

Pigs have been raised with fair success on whole milk plus minerals, without grain or roughage. Under practical conditions it is exceedingly important to furnish swine with well-cured legume hay whenever they are not on pasture. This helps to provide their vitamin needs, as well as supplying calcium and protein.

An attempt to feed horses on oats alone ended in failure, for in a few days they refused the oats and drank but little water.[42]

254. Succulent feeds.—Scientific experiments and common farm experience have abundantly demonstrated the value of adding succulent feeds to the rations of livestock. Just as our own appetites are stimulated by fruits and vegetables, succulent feeds are relishes for farm animals, inducing them to eat more feed and convert it economically into useful products. The beneficial laxative effect of silage and other succulent feeds aids in keeping stock healthy. Also, succulent feeds may stimulate digestion, because of their palatability.

It is shown in later chapters that when silage is added to a satisfactory winter ration made up of dry feeds for the feeding of dairy cows or fattening cattle or sheep, generally the production will be very appreciably increased. The increase in milk yield or in rate of gain will be large, unless the dry roughage is of very excellent quality. On the other hand, if the stock are fed an abundance of high-quality legume hay or even mixed hay, there may be but little improvement through adding silage or any other succulent feed. The decision as to whether or not to feed silage under such conditions should be reached after considering the various factors discussed in Chapter XV.

255. Exercise.—Exercise is essential to maintain health. The only exceptions to this rule are fattening animals, soon to be marketed, which make more rapid gains if not allowed to move about too freely. Abundant exercise is of especial importance with breeding animals. The exercise requirements of the various

farm animals are discussed in the respective chapters of Part III.

256. Sunlight.—Opinions differ concerning the importance of sunlight in stables for livestock. Adequate windows seem highly desirable to the author, as well-lighted stables are probably more sanitary in most cases than those that are poorly lighted. Not only may sunlight have a germicidal effect, but also caretakers are more apt to keep a well-lighted stable clean.

Sunlight which has not passed through window glass produces vitamin D in the body, as has been pointed out previously. (201)

QUESTIONS

1. Define a *maintenance ration*. Name 7 essentials for the maintenance of an animal.
2. Describe the production of heat in the body and state how it differs from the burning of fuel in a stove.
3. Describe three ways in which the loss of heat from the body is regulated.
4. Explain what is meant by the *critical temperature.*
5. Why are warm quarters not needed in winter for well-fed dairy cows or fattening stock?
6. What is the effect of very hot weather on stock?
7. How can farm animals be made more comfortable in very hot weather?
8. What is the relative heat tolerance of: (a) European breeds of cattle; (b) Zebu cattle; (c) horses and mules; (d) swine?
9. In maintaining a mature animal, for what purpose is most of the feed needed?
10. How can the amount of total digestible nutrients be determined that is required to maintain a mature animal?
11. What is the relationship between the amounts of total digestible nutrients required for maintenance by animals of various live weights?
12. How do the following affect the amount of feed an animal requires for maintenance: (a) Restlessness; (b) a fat condition of the animal; (c) exposure to cold weather?
13. Discuss the protein requirements for the maintenance of mature animals.
14. What 3 mineral nutrients should be especially considered in maintenance rations?
15. Compare the vitamin requirements for maintenance with those for growing animals or for those producing milk.
16. What is known about the nutritive needs in later life?
17. Why is a good system of ventilation advisable in closed stables?
18. Discuss the water requirements of farm animals.
19. How can trouble from urinary calculi be lessened?
20. What nutritive deficiencies are encountered when calves are raised on nothing but milk and concentrates?
21. Discuss the importance of: (a) Succulent feeds; (b) exercise; (c) sunlight.

CHAPTER IX

GROWTH—FATTENING—REPRODUCTION

I. Growth

257. Importance of thrifty growth.—Growth is one of the most important forms of livestock production. While the maximum productive possibilities of any animal depend on its inherited characteristics, its full capacity cannot be reached unless it is properly fed during the growing period.

Growth is the foundation of meat production in all classes of stock. Young cattle, sheep, and swine will not make economical gains while being fattened, unless they have been raised so that they are thrifty and vigorous. Likewise, one cannot expect good yields of milk from dairy cows, unless they have been well developed as heifers.

Similarly, brood mares, beef cows, and ewes may have their productive ability seriously reduced if they have been raised improperly. Work horses and mules cannot perform the maximum amount of labor if their growth has been stunted or if their skeletons have been injured by inadequate rations during the growth period.

258. Requirements for growth.—The nutritive requirements for growth are very different from those for mere maintenance. Not only are far greater amounts of certain nutrients required, but also a young, growing animal suffers sooner and much more seriously from nutritive deficiencies than does a mature animal.

In comparison with mature animals that are merely being maintained at constant weight, growing animals need: (1) Decidedly more protein and protein of better quality; (2) much more total digestible nutrients; (3) a more liberal supply of minerals, especially calcium and phosphorus; and (4) larger amounts of vitamins.

Each of these needs is discussed in the following articles, and detailed information is given in Part III concerning the requirements of each kind of young stock. Many different rations are suggested there and in Appendix Table VII which will produce good growth and development. The nutritive requirements for growth of each kind of the larger farm animals are stated in the Morrison feeding standards. (Appendix Table III.) The requirements of poultry are given in Chapter XXXVI.

259. Protein requirements.—Since growth consists largely of an increase in the size of the muscles and other protein tissues, it is obvious that far more protein is needed for growth than for maintenance. Also, the quality or kind of protein is more important for growing animals than for those that are merely being maintained. (111) If there is an inadequate supply of any of the essential amino acids, an animal will be unable to make normal growth, even though the *amount* of digestible protein is plentiful. As has been emphasized in Chapter V, after the rumen has become well developed in ruminants, the quality of protein in the ration is of far less importance for them than for poultry or pigs.

Very young animals require the largest proportion of protein in their rations, because of the extremely rapid growth of protein tissues in their bodies. The proportion of protein that is needed gradually decreases as the animals become older and store less protein and more fat.

The amounts of digestible protein recommended in the Morrison feeding standards are based on the results of actual feeding experiments with the various kinds of young animals. Since the amounts of protein in individual lots of

the same kind of feed vary considerably, safe allowances for such variations have been included in the recommendations. In the standards it is assumed that protein of satisfactory quality will be furnished in the ration.

Recent experiments, reviewed in Chapter XXXIV, have shown that when a ration for growing pigs supplies ample amounts of vitamin B_{12} and the other essential vitamins, somewhat less protein is needed for excellent gains than was previously thought to be necessary. It thus seems that the benefit from the former more liberal allowance of protein was due to the vitamins supplied, especially by protein supplements of animal origin, and not to the larger amount of protein.

260. Factorial method of estimating requirements.—A method sometimes used in studying the protein requirements for growth is to determine the amounts of protein stored daily in the bodies of growing animals. From what limited data are available, it is then estimated that the animals should utilize the digestible protein in their feed with a certain percentage of efficiency. On this basis, amounts of digestible protein are computed, which, it is believed, should produce normal growth.

Based upon this method, Mitchell and associates of the Illinois Station have recommended amounts of protein for growing animals which are much lower than are commonly fed.[1] This seems to be an unsafe method of estimating requirements. In New York experiments with fattening lambs and with growing dairy heifers, much more protein was actually needed for satisfactory results than had been recommended from the use of this method.[2]

LEGUME FORAGE IS UNEXCELLED FOR GROWING STOCK

Shorthorn cattle on clover pasture. An abundance of good legume forage is excellent insurance against any deficiency of protein, of calcium, or of vitamins for calves, lambs, or foals.

261. Total digestible nutrients or net energy.—For normal growth the ration must supply much more total digestible nutrients or net energy than needed for mere maintenance. This is because an animal can use for growth only the amounts of nutrients left after its maintenance needs have been met. Young animals therefore need more liberal rations than for maintenance, and also generally rations that are more concentrated.

It has been pointed out in the previous chapter that mature cattle, sheep,

and horses can be maintained largely or entirely on roughage, even that which is rather inferior. On the other hand, very young calves, lambs, and foals cannot make good growth on roughage alone, even if it is of high quality. If a young animal does not receive sufficient total digestible nutrients or net energy, its rate of growth will be slow and it may be permanently stunted in size if the underfeeding is continued too long.

262. Stunting of young female animals.—Under practical conditions young female animals are apt to be stunted in size unless they receive sufficient feed to make normal growth up to the time they bear their first young. If they are undersized at this time, they will usually get no opportunity to make up for the lost growth. In milk production there are heavy demands on their bodies for nutrients, and these demands take precedence over any use of nutrients for continued growth of the mother. Because of repeated reproductions and lactations, the animals are unable to complete their growth, and they therefore never reach normal size.

This is especially apt to occur with dairy heifers that have not made normal development by the time of first freshening. Because of the large amount of milk a good heifer produces, she will not be able to make much growth while in milk, unless she is fed with considerable liberality. In many a herd the cows are under-sized and lack high productive capacity, largely because the owner has fed his heifers too scantily.

263. Mineral requirements.—The great importance for growing animals of an ample supply of minerals, especially calcium and phosphorus, has been shown in Chapter VI. A lack of minerals may be even more serious to a young animal than a lack of protein or a lack of total digestible nutrients. Thus, a deficiency of calcium or phosphorus may permanently cripple or deform the animal. Also, the bones may be so fragile that they will readily break in later life. Wherever there is a possibility that the rations for young stock may be lacking in either of these minerals, a mineral supplement should be supplied, as has been previously advised.

There is a heavy drain on the store of calcium and phosphorus in the body during high milk production. It is therefore important to feed dairy heifers and other female breeding animals so that they will start their first lactation with a good store of these minerals.

For calves, lambs, and foals the best insurance against a lack of calcium is to feed sufficient legume hay throughout winter and to provide good pasture during the growing season. Well-cured legume hay not only has an abundance of calcium, but also sun-cured hay is the best source among common feeds of vitamin D, which animals must have in order to utilize the calcium and phosphorus in their rations.

Whenever there is any possibility that the rations for young stock may be lacking in phosphorus, a safe phosphorus supplement should be added, as advised in Chapter VI and also in Part III, where recommendations are made for each class of stock.

In the case of suckling pigs not on pasture, there may be disaster from anemia caused by lack of iron and copper, unless the precautions are taken which are recommended in Chapter XXXIV. In districts where there is a definite deficiency of iodine, it is wise to supply this mineral in the form of iodized salt, or by other means. In certain areas it is necessary to furnish certain trace minerals, as explained in Chapter VI.

264. Vitamin requirements.—In the discussions of the vitamins in Chapter VII, it has been emphasized that it is just as necessary that growing animals receive an adequate supply of vitamins as that they get ample protein and minerals.

Suckling animals will receive plenty of vitamin A in the milk if their mothers are fed suitable rations. On the other hand, if the mothers have been fed rations lacking vitamin A value, the milk may be so low in the vitamin that the young will suffer severely.

When young animals are weaned, care must be taken that sufficient vitamin A value is furnished by feeds rich in carotene, such as well-cured hay, silage, good pasture or other green feed, or by yellow corn. In the case of calves changed from whole milk to skimmilk or milk substitutes at an early age, it is especially important that they be furnished with choice, green-colored hay as soon as they will eat it, to provide both vitamin A and vitamin D.

Young stock on pasture will ordinarily not suffer from a lack of vitamin D, because of the effect of the ultraviolet rays in sunlight. Under winter conditions, however, young pigs are often severely crippled or even paralyzed by rickets, caused by a lack of this vitamin. Also, dairy calves and foals sometimes suffer from rickets. These conditions can usually be entirely prevented by the use of good-quality field-cured legume hay, as described in the chapters of Part III. Beef calves and lambs rarely have rickets, because they are outdoors in the sunlight more, even in winter.

It is shown in Chapter VII and in the swine and poultry chapters that some rations for poultry and also for pigs not on pasture are improved decidedly by the addition of certain B-complex vitamins, especially vitamin B_{12}. Poultry have especially high requirements for riboflavin, and therefore a riboflavin supplement is commonly needed, unless the birds are on excellent pasture.

Information is given in Part III concerning the vitamin requirements of the various kinds of young stock. The amounts of carotene required, except for poultry, are shown in the feeding standards in Appendix Table III, and the vitamin requirements of poultry are stated in Chapter XXXVI.

265. Utilization of food by young animals.—It is well known that young animals make decidedly more rapid gains, considering their size, than do older animals, even when the latter are fed liberal fattening rations. For example, a month-old calf fed liberally on milk will gain about 1 lb. a day per 100 lbs. live weight, while a daily gain of 0.3 lb. per 100 lbs. of weight is large for a 2-year-old fattening steer.

Young animals can build into their protein tissues and skeleton a large part of the protein and mineral matter in their rations. Up to a month of age calves may store 70 per cent or more of the protein, calcium, and phosphorus contained in the milk they consume. As they grow older, the percentages of these nutrients which are stored decrease. Thus, 2-year-old fattening steers will store only about 13 per cent of the total protein in their ration. After growth is completed, but little storage of protein or mineral matter can take place, for the skeleton, the muscles, and the internal organs have reached full development.

Numerous feeding experiments, which are reviewed in Part III, have shown that young animals require considerably less feed per 100 lbs. of gain in body weight and therefore make much cheaper gains than animals which are older. For example, growing and fattening pigs require for each pound of gain in live weight about one-third more feed between the weights of 200 and 250 lbs. than they do between the weights of 50 and 100 lbs. Similarly, the feed cost per pound of gain in weight is about one-third greater in fattening 2-year-old cattle for market than in fattening calves.

There are the following reasons for the more rapid gains and the more economical meat production of young animals:

(1) Their gains are more watery than those of older animals, and also contain more protein and less fat, which has a decidedly higher energy value than protein. More net energy is therefore required to make a pound of gain on a mature fattening animal than on one which is young and growing.

(2) The food eaten by young animals is ordinarily lower in fiber, and hence more digestible and higher in net energy, than that eaten by older animals.

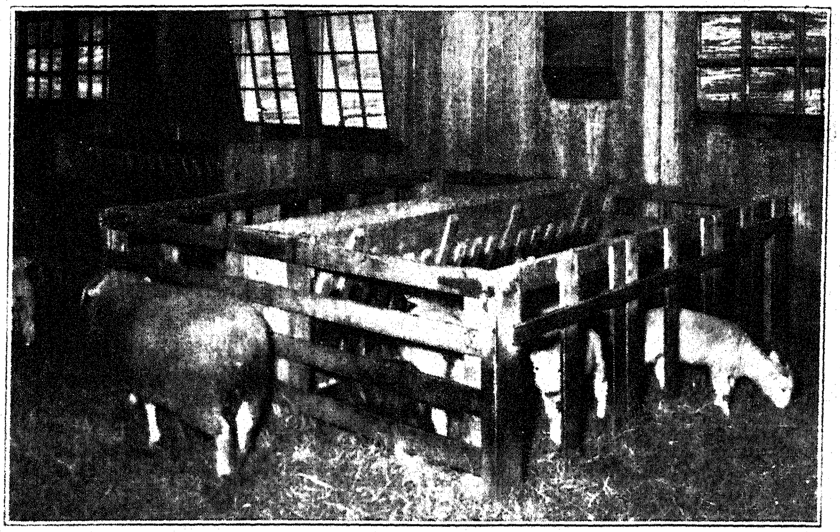
(3) Since young animals eat more feed in proportion to live weight, they

have left for building into body tissues a much larger part of their feed, after their maintenance requirements have been met.

These factors account fully for the cheaper gains of young animals. Contrary to common popular opinion, there is no evidence that a young animal makes any better utilization of the net energy supplied in the feed than an older one, after the maintenance requirements are deducted.

gains during the following pasture season.

The rate of growth and the efficiency with which the nutrients are utilized depend not only on the adequacy of the ration, but also on the inherited growth capacity of the animal. By skillful breeding, much improvement can be made in the efficiency with which farm animals transform food into body tissue. An excellent illustration of such possibilities is the improvement of swine in



LIBERAL FEEDING IS NECESSARY FOR RAPID GROWTH

In addition to their mothers' milk, these early-spring lambs are being supplied with a mixture of grain and other concentrates in a lamb creep, so they will make rapid growth. (From J. P. Willman, Cornell University.)

Denmark, which is mentioned in Chapter XXXIV. Through careful selection of breeding stock, based on feeding and slaughter tests of the progeny, the amount of feed required per 100 lbs. gain has been materially reduced and the quality of the carcasses also decidedly improved.

266. Importance of utilizing growth capacity.—Young animals should always be provided with ample protein, minerals, and vitamins, so as to utilize their great growth capacity in making efficient gains. Except in some types of beef production, it is generally most profitable to supply young animals continuously with sufficient total digestible nutrients to keep them growing normally. Under range conditions, as is shown in Chapter XXIX, it may be most economical to winter beef calves or yearlings on only enough feed to keep them thrifty, without making rapid gains. (284) This is because they then may make very cheap

267. Storage of protein in mature animals.—After an animal reaches mature size, very little storage of protein can occur, since the muscles and other protein tissues are fully developed. If an animal is healthy but has poor muscular development, the size of the muscles can be increased somewhat by suitable exercise and food. Also, an animal

whose muscles have wasted away through sickness or starvation will rapidly repair its tissues upon a return to favorable conditions, thereby storing protein. In addition, if an animal which has been on a low-protein ration is later fed ample protein, a small amount of protein can be stored through increasing the protein reserve in the blood and tissues. (241)

A small amount of protein is stored in the continual growth of such external protein parts as hair, wool, feathers, and hoofs. In the case of a mature animal that is being fattened, a small amount of protein is stored in the fatty tissues.

268. Rates of growth.—The different kinds of farm animals have rates of growth which are characteristic for the species. Also, the various breeds of the same species differ to some extent in mature size that is reached and in the earliness of maturity. Data showing the normal weights and heights of young stock at various ages, such as are presented in Chapter XXVII for dairy cattle and in Chapter XXXIII for horses, serve as convenient guides in determining whether stock have made normal growth.

Studies by Brody and associates at the Missouri Station, as well as investigations by others, have shown that the rate of growth by farm animals generally increases up to the age of puberty, or sexual development.[3] After this, the rate gradually decreases as maturity is approached.

These studies also show that in proportion to their mature size and the length of time taken to reach it, the rates of growth of most species of animals have great similarity. However, the rate of growth in man differs in a striking manner from the rates for farm animals, humans having a much longer juvenile period in proportion to their average length of life.

The various parts of the body develop at unequal rates. The skeleton and head make more rapid early growth than the muscles, and fattening is most rapid at later stages.[4] By greater or less liberality of feeding at various ages it may therefore be possible to change the form and composition of the body somewhat. (283)

The rate of growth and the size of the body are controlled by a hormone produced by the pituitary gland. (54) If an insufficient amount of the hormone is secreted, the animal will be dwarfed. On the other hand, an excessive secretion of the hormone results in a giant animal that is weak physically.

The development of the body may also be affected by the amount of thyroxine, the hormone produced by the thyroid gland, which controls the rate of metabolism in the body. Growth is checked and an animal becomes fatter than usual if normal secretion of thyroxine is prevented by certain drugs. The effect of thiouracil, such a drug, upon pigs is discussed in Chapter XXXIV.

269. Milk the natural food for young mammals.—Milk is practically indispensable for young mammals during the earliest stages of growth, and it is unexcelled as a food during the entire suckling period. Whole milk, containing the fat, has the following nutritive virtues:

(1) It is easily digested and assimilated and has a very high nutritive value per pound of dry matter; (2) it has an abundance of high-quality protein; (3) it is rich in calcium and phosphorus; (4) it provides plenty of energy in the fat and milk sugar; (5) it is high in vitamin A value, if produced by animals fed good rations; (6) it is rich in riboflavin and is a good source of niacin, vitamin B_{12} and other B-complex vitamins; (7) the milk sugar tends to increase the assimilation of calcium and phosphorus and to prevent putrefaction in the digestive tract.

As has been shown in Chapter VIII, milk is not a perfect food for exclusive feeding to animals over long periods. It has but little iron; the content of vitamin D is rather low; and it is not rich in ascorbic acid. In livestock feeding the lack of iron is important only in the case of young pigs not on pasture, as explained previously. The relatively low content of vitamin D can readily be

made good by allowing the young animals access to sunlight, or by including in the ration well-cured legume hay or some other source of vitamin D. The fact that milk has but little ascorbic acid is not of importance in feeding farm animals.

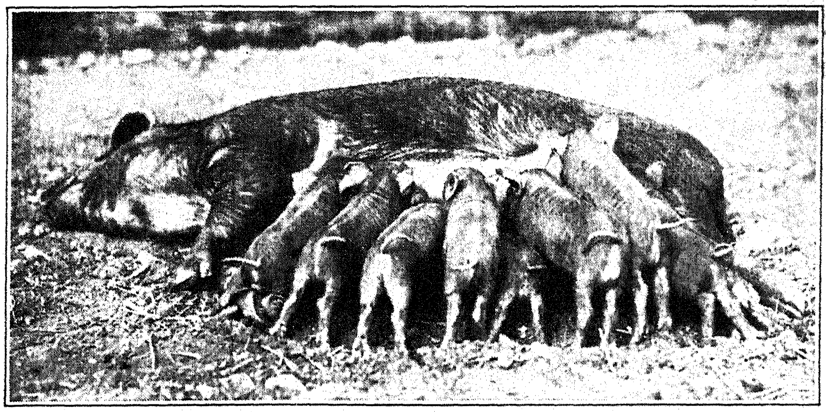
A very young animal has only a limited ability to digest and assimilate fat. If it is fed milk containing a much greater percentage of fat than is normal for that species, serious digestive disturbances may result. Since human milk has less fat than cow's milk, this fact must be borne in mind in feeding very young infants. For delicate infants, cow's milk too high in fat may produce unsatisfactory results.

Even for very young calves, particularly those that are not vigorous, it is best to use milk that is not too rich in fat.[5] Thus, in a Jersey or Guernsey herd it is wise to use milk from a low-testing cow for a week or two, or to add warm skimmilk or even water to lower the fat.

270. Importance of colostrum.—Colostrum, the milk yielded by the mother for a short time after birth, differs greatly in composition from ordinary milk, and it has very important functions. The most indispensable of these is to supply antibodies to protect the new-born animal against certain diseases, especially of the digestive system. Because of this, calves, lambs, foals, or pigs that do not secure colostrum are apt to die from the lack of it.

Colostrum is very rich in protein, cow's colostrum having as much as 17 per cent. A large part of the protein consists of globulins, which are present only in traces in ordinary milk. The antibodies, which are so important for the new-born animal, accompany these globulins. At birth, the blood of the young animal contains practically no antibodies, though they are present in the blood of the mother. For a short time after birth, the globulins, carrying the antibodies, can pass through the intestinal wall and enter the blood stream. However, in a day or two the intestine becomes impermeable to the globulins. The new-born therefore needs colostrum before this occurs. Later in life, the young animal itself develops more or less immunity to digestive infections.

Colostrum is also much richer than ordinary milk in vitamins, especially vitamin A, and in minerals. The high content of vitamin A is of great importance to animals at birth, for they are



MILK IS THE NATURAL FOOD FOR YOUNG MAMMALS

A study of the composition of milk shows that young animals should have rations which provide: (1) A liberal amount of easily-digested nutrients; (2) an abundance of protein of high quality; (3) plenty of minerals, especially calcium and phosphorus; and (4) an adequate supply of vitamins. (From Wisconsin Station.)

born with only a very small amount of it in their bodies.[6] Because of the richness of colostrum in vitamin A, a calf may receive in the first day as much of the vitamin as it would secure in several days from normal milk.

If a calf or other new-born animal cannot receive colostrum from its dam or a similar female, it should get supplements furnishing vitamin A and other vitamins, and it may be necessary to supply antibodies by the hypodermic injection of blood serum from the same species.

By adding a concentrated vitamin A supplement to a good ration for dairy cows for some weeks before calving, the vitamin A value of the colostrum and also the store in the body of the calf can be considerably increased.[7] However, pasture may sometimes not raise the vitamin A value above that of colostrum produced on a good winter ration.[8] If cows have been continuously fed a ration deficient in carotene, their colostrum and their later milk will be low in vitamin A and carotene.

II. Fattening

271. The object of fattening.—We all know that the lean meat from a well-fattened animal is better flavored and more juicy than that from a lean one. This improvement in the quality of the lean meat, and not the storage of thick masses of fat, is the main object in fattening animals before they are slaughtered for meat.

To some extent during growth and especially during fattening, fat is stored in the lean-meat tissues, chiefly between the bundles of fibers of which the muscles are composed. This storage of fat, which forms the so-called "marbling" of meat, adds to the juiciness and flavor, besides increasing the digestibility and nutritive value. During fattening there is also some increase in soluble material of the muscles, which adds to the flavor of the meat.

It has been commonly believed that the lean meat from a well-fattened animal is more tender than from a lean one of the same age. Recent experiments indicate, however, that in the case of young animals of some kinds fattening may not make the lean meat appreciably more tender, though it does greatly improve the juiciness and flavor. Fattening beef cattle generally makes the lean meat somewhat more tender, the effect being more pronounced in older animals. Fattening may not increase the tenderness of lamb or pork.

Beef becomes decidedly more tender, as well as better-flavored, when it is aged for a few days at the proper temperature in a cooler. This is also the case with mutton from older sheep. The increase in tenderness is due to enzyme action on the tough and resistant protein in the connective tissue of the meat. Unless a carcass has a sufficient covering of external fat, it will tend to spoil before it has been sufficiently aged.

272. What fattening is.—In the fattening of mature animals or those which have nearly completed their growth, the gain consists primarily of fatty tissue. In the case of such animals there is but little storage of protein and mineral matter. For example, the gains made by steers which are fattened when nearly full grown will be about two-thirds fat, and will have only about 8 per cent protein, less than 2 per cent mineral matter, and somewhat over 20 per cent water.[9]

Most of the animals raised for meat in this country are now fattened for market at relatively young ages. For instance, but few steers are older than 3 years when slaughtered, and a large proportion are only 1 to 2 years old. Likewise, practically all the lambs not retained for breeding are fattened and marketed before they are a year old. Most of the pigs reach the market when much less than a year of age. Since such animals are still growing rapidly in muscle and skeleton while they are being fattened, the proportion of protein and mineral matter will be much higher in their gains than in those of older animals.

This is shown by Missouri experiments in which analyses were made of the entire carcasses of steers slaughtered before fattening and at various degrees of fatness, to find the composition of the

gain made during fattening.[10] The 500 lbs. of gain made in fattening thrifty 740-lb. steers until they weighed about 1,250 lbs. contained 46 per cent of fat, 12 per cent of protein, and 40 per cent of water.

When steers were made excessively fat by putting on a second 500 lbs. of gain, this additional gain had 68 per cent of fat, less than 7 per cent of protein, and only 22 per cent of water. It was therefore nearly all fatty tissue, with but little lean meat and a low water content.

The fact that the proportion of fat in the gain made by an animal steadily increases during the fattening period is of much practical importance. It is the chief reason why the feed cost per pound of gain increases rapidly after an animal has become fairly well fattened. Such flesh contains much more fat and less water, and it is correspondingly more expensive to produce.

Also, when an animal has become fairly fat, it eats less feed per 1,000 lbs. live weight. Consequently, it has less nutrients left for meat production after the maintenance requirements have been met. In addition, the actual maintenance requirements of a fat animal per 1,000 lbs. live weight may be higher than for one in moderate flesh. (239)

For these reasons, one should have the demands of the market very definitely in mind in fattening stock for market. The animals should be fattened sufficiently to produce the best net returns, considering the probable sale price for animals of various degrees of fatness. However, they should not be made fatter than necessary, or the high cost of the gains will generally reduce the profits.

273. Wastefulness of excessive fattening.—Not only are the gains very expensive when animals are carried to extreme fatness, but also the carcasses do not meet the desires of most consumers. The lean meat, will, it is true, be of the highest quality. However, too large a proportion of the various cuts will consist of masses of fat that are not usually eaten, especially in the case of beef and mutton.

Any excess fat beyond that which is required to make beef or mutton attractive, juicy, and well-flavored is therefore largely waste, though it has been a heavy expense to the producer. Years ago, when cattle were usually fattened after they were well grown, it was necessary to carry them to a high finish to make the meat tender and juicy. Now, however, with our changed methods of beef production in which cattle are fattened while yet young and growing, such extreme fattening is no longer needed to produce beef of good quality.

274. Composition of steers of different ages.—For several years Haecker of the Minnesota Station conducted extensive investigations on the food requirements of steers of different ages, in which the entire carcasses of many animals were analyzed.[11] The table on the next page shows the average composition of the steers at various stages of growth.

The table shows that the percentage of water steadily decreases as the animal matures, falling from over 71 per cent in the calves to 43 per cent in the 1,500-lb. steer. The percentage of fat increases rapidly during the growth and fattening of the animal, increasing from 4.0 per cent soon after birth to over 37 per cent in the 1,500-lb. steer. The protein and ash show less change than the water and fat, but the percentages decrease gradually as the animals grow older.

Haecker found that the storage of protein by the animal, which is rapid in early life, shows a marked slowing up when the animal reaches a weight of about 800 lbs. On the other hand, the gain in fat is most rapid after the steer reaches a weight of 600 lbs.

275. Formation of body fat.—Numerous experiments have shown that after enough nutrients have been supplied to maintain the body, any excess—no matter whether of fat, carbohydrates, or protein—may be transformed into body fat. In the fattening of farm animals most of the fat is undoubtedly formed from carbohydrates, for these are the most abundant nutrients in all common rations. When more protein is furnished than is needed for the repair of the body

tissues, the remainder may, after the nitrogen is split off, likewise be changed into body fat. The fat in the food can also be made into body fat, after more or less change.

The relative values of different feeds for the formation of body fat depend on the amounts of net energy or of total digestible nutrients that they furnish. For this reason, such a feed as corn grain is unexcelled for the fattening of stock.

fat in feeds also affects the character of the milk fat produced by cows. On the other hand, the character of the body fat formed by ruminants (including cattle, sheep, and goats) is apparently not changed appreciably by the kind of fat in the feed.[12]

277. Nutrient requirements for fattening.—The first requirement of a ration for fattening animals is an abundance of total digestible nutrients or net energy. The amount of protein needed

Average composition of steers at various stages *

Normal weight	No. of steers	Water	Dry matter	Protein	Fat	Ash
Lbs.		Per cent	Per cent	Per cent	Per cent	Per cent
100	5	71.84	28.16	19.89	4.00	4.26
200	4	70.43	29.57	19.14	6.01	4.42

1,500	1	43.48	56.52	15.72	37.59	3.21

* Not including contents of the digestive tract.

276. Effect of food fat on body fat.—At least in the case of swine and chickens, if the feed contains considerable fat the kind of fat in the food may have a pronounced effect upon the character of fat stored in the body. This is because the fatty acids in the food fats are to some extent deposited unchanged in the fatty tissues. If the feed contains considerable fat that is liquid at ordinary temperatures, the body fat may become so soft as to injure the quality of the carcass.

Thus, if swine are fed any considerable amounts of soybeans or peanuts, the pork will be so soft that the carcasses will be undesirable from the market standpoint. Just opposite in effect, cottonseed meal and coconut oil meal tend to produce hard pork. The kind of

and also of vitamins and minerals will depend chiefly on the age of the animals, the requirements being much greater for young animals than for those that are well grown when fattening begins.

The nutritive requirements for fattening each class of stock are discussed in the chapters of Part III, and many practical rations are recommended there and in Appendix Table VII which are adapted to the conditions in various districts. The amounts of nutrients advised for fattening the different classes of stock and at various ages are stated in the Morrison feeding standards.

278. Total digestible nutrients or net energy.—It has already been emphasized that fattening animals need an abundance of total digestible nutrients or net energy. Unless they have a large

surplus of nutrients after their maintenance needs have been met, the rapid formation of fatty tissues is impossible.

The supply of total digestible nutrients must be considerably more liberal for fattening than for normal growth. Thus, a beef calf, after weaning, will make satisfactory growth during winter on good roughage alone. On the other hand, a calf being fattened for baby beef needs a large amount of grain and other concentrates, in addition to good roughage. In fattening young animals it is especially necessary that they be fed liberally. Otherwise, they may merely continue to grow, because of their strong growth impulse, and may fail to fatten properly.

It has been explained in Chapter IV that animals digest and utilize a slightly smaller percentage of the nutrients in the ration when they are given liberal rations than when their feed is limited. (**101**) However, in the fattening of stock this difference is generally more than offset by other factors.

The animal that is fed liberally will have a much larger proportion of the total nutrients in its ration available for fattening, after the amount needed for maintenance is deducted. Less feed is therefore commonly required per 100 lbs. of gain when an animal is fed with sufficient liberality to produce good gain than when the feed supply is so scanty that slow gains result. Also, slow gains greatly prolong the fattening period, and so increase the cost of labor and the other expenses.

FATTENING STOCK NEED A LIBERAL SUPPLY OF CONCENTRATES

Hereford cattle being fattened on an Iowa farm. The first requirement of a ration for fattening animals is an abundance of total digestible nutrients or net energy. These steers are being fed a liberal amount of corn.

Especial consideration is given in Part III to the amounts of grain or other concentrates required for fattening the various classes of stock. Whether or not it will be most profitable to feed fattening cattle or lambs all the grain they will eat will depend first of all on the relative prices of grain and roughage. It will also depend on the amount of premium paid in the market for well-fattened animals. This important problem is discussed in detail in Chapters XXVIII and XXXI.

279. Protein requirements for fattening.—It has been pointed out previously that most of the animals raised for meat in this country are now fattened

for market when relatively young. Such animals are making rapid growth of muscles and other protein tissues, and therefore they need an abundant supply of protein.

In the fattening of mature animals there is but little storage of protein in the gain produced. Much less protein is therefore needed than for growing animals. Indeed, experiments have shown that mature fattening animals will make fairly satisfactory gains on rations supplying only 0.75 to 1.5 lbs. of digestible protein daily per 1,000 lbs. live weight.[13] However, it is probably not advisable in the practical fattening of mature animals to reduce the protein supply to this level.

It has been pointed out in Chapter IV that the digestibility of a ration is considerably reduced if it contains too small a proportion of protein and too large a proportion of carbohydrates and fat. Also, a ration is usually more palatable if it has a reasonable amount of protein, and therefore animals will eat a greater amount of it than of a ration very low in protein. This is important in producing rapid gains.

If fattening animals are fed rations that are rich in carbohydrates and fat, but too low in protein, they are apt to go "off feed" and may even suffer from digestive disturbances. Considering all these factors, it is recommended that even for mature animals a ration for fattening should not generally have a wider nutritive ratio than 1 : 10.0.

280. Mineral and vitamin requirements for fattening.—Mature fattening animals do not require a much greater amount of minerals than they need for mere maintenance, and their vitamin requirements are also low. On the other hand, young fattening animals have even greater needs for minerals and vitamins than those that are merely making normal growth. Particular care must therefore be taken that they have an ample supply of these nutrients, or the gains will be unsatisfactory, and the animals may even become decidedly unthrifty.

For example, the experiments that are reviewed in Chapters XXVIII and XXX show in a striking manner that a lack of calcium may be the chief cause of the poor gains often made by fattening cattle or lambs when there is no legume hay in the ration. As is pointed out there and in Chapter VI, calcium can readily be provided in such forms as ground limestone or ground oyster shell. (157)

281. Factors influencing fattening.—In addition to the suitability and the liberality of the ration, certain other factors have a great influence on the rapidity and economy of gains during fattening.

Unthrifty animals make slow and expensive gains. Young animals that are thin and even somewhat small for their age, due to a previous scanty supply of feed, may make rapid and cheap gains when fed a liberal fattening ration. It will, of course, require considerably longer for them to reach a desired market condition than for animals which are in better flesh at the start of fattening. If young animals have been stunted by a lack of minerals or vitamins, they are apt to be unthrifty and therefore unprofitable in the feed lot.

The ability of an animal to make economical gains and reach a good finish also depends upon temperament. While a wild animal, nervous and active, can be fattened only with extreme difficulty, farm animals are more quiet and usually fatten readily. The restless animal is rarely a good feeder, while the quiet one, which is inclined to "eat and lie down," will usually make rapid gains. This is because the quiet animal has, from a given amount of food, a greater surplus of nutrients available for fat building. Fattening animals must not be allowed to exercise too much, as this wastes nutrients which they might store in their bodies.

III. Studies on Growth and Fattening

282. Effects of nutritional deficiencies on young animals.—Many experiments have been conducted to find the effect of feeding young animals unbalanced rations, which did not supply

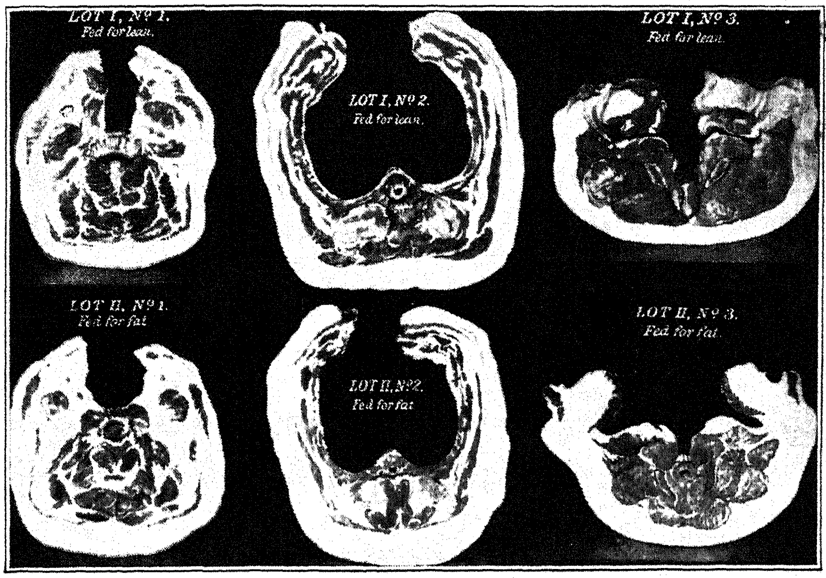
enough protein or which were deficient in minerals or vitamins. These investigations proved clearly that when young animals are fed such rations they are unable to make normal growth.

If the deficiency is too severe or too long continued, disastrous results will be produced. The animals will be permanently stunted or they may be crippled by rickets or other diseases caused by the deficiencies. These experiments were of much practical importance, for they showed clearly the folly of failing to provide proper rations for young animals.

Years ago several experiments were carried on in which pigs that were already fairly well grown were fed corn alone, in comparison with well-balanced rations.[14] Some of these early experiments in animal nutrition were conducted over 65 years ago at the University of Wisconsin by Professor W. A. Henry, the author of the early editions of *Feeds and Feeding.*

In these studies the pigs fed corn alone not only made slow and expensive gains, but also the feeding of corn alone greatly changed the carcasses. The carcasses of pigs thus fed had a wastefully high proportion of fat and much less lean than those of pigs fed balanced rations. Also, the pigs fed corn alone had very weak bones, much smaller livers and other internal organs, and less blood.

It must be remembered that these results were secured with pigs that had already made much of their growth when started on the inadequate ration. If young pigs had been used, those fed corn alone would have made practically no growth or would have died or been permanently crippled or stunted.[15]



PIGS FED CORN ALONE DO NOT DEVELOP NORMAL CARCASSES

Upper row, cross sections of carcasses of pigs fed for lean; i. e., on well-balanced ration, by Henry at the Wisconsin Station. Left, section at shoulder; middle, section between fifth and sixth ribs; right, section at loins. Lower row, carcasses of pigs fed corn alone. Note larger size of muscles of pigs fed well-balanced ration.

To find whether the poor results on corn alone were due to the lack of minerals, Henry conducted 3 experiments at the Wisconsin Station in which well-grown pigs were fed corn alone or corn and mineral supplements.[16] The pigs were confined in pens, with floored exercise

yards, so they could eat no dirt. The pigs fed corn alone soon failed to grow and became unduly fat and dwarfed. Those receiving bone meal or wood ashes in addition grew quite well for a time, but later their gains were poor.

On corn alone 629 lbs. of corn were required for 100 lbs. gain in weight, while only three-fourths as much was required when bone meal or wood ashes was added. Also, the bones of the pigs fed corn alone were only half as strong as those of the others. These trials clearly showed that adding a liberal supply of minerals to the ration was of some benefit, but it did not entirely remedy the deficiencies of corn for growing animals.

In later years numerous trials were carried on to study this matter further. These investigations clearly showed that to make a satisfactory ration for growing pigs, there must be added to corn not only minerals, but also more protein and protein of a kind that will correct the deficiences of the corn protein. For pigs not on pasture, careful attention must be given to meeting the vitamin needs that are discussed in Chapters VII and XXXIV.

283. Influence of methods of feeding upon the carcass.—Interesting experiments, especially those of Hammond and associates at Cambridge University, England, have shown that the proportions of various parts of the body can be modified appreciably by methods of feeding.[17] Also, the proportions of bone, muscle, and fat can be thus changed.

Growth proceeds at different rates in the various parts of the body. The head develops more rapidly at an early age than do other parts, and then the feet and legs grow fast. The trunk, and especially the hindquarters and the loins, are late in developing and are the last parts to reach mature size.

Comparing the different kinds of body tissues, it is found that during early growth the skeleton develops more rapidly than muscles or fatty tissues. However, the muscles develop relatively early, and fat deposition comes last.

In an experiment by McMeekan, working under the direction of Hammond, it was found that the best bacon carcasses were produced when pigs, after weaning, were fed a liberal ration for 16 weeks and then fed a limited ration until they reached market weights.[18] This method of feeding produced a large proportion of lean, apparently because the food supply was abundant during early growth when muscle and bone develop most rapidly.

An opposite method of feeding—a limited ration at first and then full feeding to market weights—produced carcasses that were decidedly of the lard type, with a large proportion of fat and a small proportion of lean. Pigs that were fed a limited ration continuously not only took a much longer time to reach the same market weight, but also they were not sufficiently fattened and they had a poor development of loin and hindquarters. These are the parts of the body which develop last. Pigs which were fed liberally throughout had better bacon carcasses than those which received a limited ration at first.

The amount of feed required per 100 lbs. of gain under various methods of feeding is, of course, fully as important from the practical standpoint as the effect upon the carcass. The effect of the limited feeding of pigs upon the economy of pork production is therefore discussed in some detail in Chapter XXXIV. The data which have thus far been published concerning these English experiments deal only with the effects upon the carcass and not with the economy of production under the various systems of feeding.

284. Effects of scanty feeding of growing animals.—It is now well known that young animals may be permanently injured or even killed by a serious lack of minerals or vitamins. A severe deficiency in amount or quality of protein may also have grave effects. The question then arises as to what the effect will be if young animals are temporarily fed a ration that does not provide enough total digestible nutrients for normal growth, but which has an adequate supply of protein, minerals, and vitamins.

Does such scanty feeding permanently injure or stunt the animal?

This question is of great practical importance, especially in the range districts of the West. Under range conditions young cattle and other stock often get most of their winter feed by grazing the dry grass and other forage on a winter range. The amount of feed available is often scanty, and the digestibility and the net-energy value of such mature and weathered forage is very low. (368) Combined with these lacks, there will be a deficiency of protein, probably of minerals, especially of phosphorus, and often of vitamin A, unless adequate supplements are provided in addition to the weathered forage. As a result of these lacks, young cattle often weigh less in the spring than they did the previous fall. Even under farm conditions, young steers that are to be pastured the next summer are often wintered chiefly on cheap, low-grade roughage and make but little gain in weight.

Extensive experiments were conducted some years ago at the Missouri and Kansas Stations to study the effects of such scanty feeding,[19] and recently similar experiments have been carried on by Winchester and Howe of the United States Department of Agriculture with pairs of identical twin steers.[20] In these recent studies care was taken to provide plenty of protein, minerals, and vitamin A in the scanty rations. Therefore these rations lacked only energy.

The investigations have shown that unless the underfeeding is continued too long, the animals are not permanently stunted but will reach normal size if they are later feed liberally. Steers that had been fed scantily for a time made rapid gains in weight when changed to a liberal ration. During this period of rapid gains they required even less feed per pound of gain than normal. Of course, the steers that were fed scantily for a time and then fed liberally needed a much longer time to reach satisfactory market weight and condition than did the steers fed a liberal ration continuously.

In the recent studies one steer in each pair was fed a liberal ration all the time, while the other steer in the pair was fed from 6 months to about a year of age a scanty ration. This provided from 50 to 75 per cent as much total digestible nutrients as in the liberal ration. On the lowest level of feeding the steers barely maintained their weights for the 6-month period, while the liberally fed steers gained an average of 1.7 lbs. during this time. After about a year of age, all the steers were full-fed until they reached a slaughter weight of 1,000 lbs. It took from 10 to 20 weeks longer for the steers that had been retarded to reach this weight than it did for their liberally fed pair-mates.

Surprisingly, the steers that had been fed scantily for a time required a total of only slightly more total digestible nutrients than their liberally fed mates to reach this weight. Also, the carcass grades and meat quality were not lowered appreciably by the period of scanty feeding.

Differing somewhat from these results, the steers that were scantily fed for a time in the Missouri and Kansas experiments required more total feed to get them ready for market than was needed by others which were fed a normal ration the entire time.

From these studies on scanty feeding and the results of the feeding experiments summarized in Chapter XXIX, we can conclude that feeding young beef cattle so scantily in winter that they make little or no gain is not generally advisable, except in emergencies or when supplemental feeds are very expensive in comparison with summer pasturage.

The purebred livestock breeder who seeks to develop his animals toward an ideal should always be careful to give growing animals ample feed. Detailed information is given in Part III concerning the amounts of feed and especially of concentrates that should be fed to the different kinds of growing animals under various conditions.

285. Continuous growth important. —A California experiment shows that feed may be utilized more efficiently

when young beef cattle on the range are given supplemental feed during periods when the range pasturage is too mature or too scanty to permit normal growth.[21] In the region where the test was conducted, the growth of the range plants takes place from November, after the first rains, until late spring. From June or July the forage is completely dry and mature, and it not only lacks palatability but also is very low in digestible protein. Beef calves grazed on this mature forage without supplemental feed generally lose weight after weaning.

In this experiment it was very profitable to feed steer calves, during the period when the range forage was dried up, a sufficient amount of a protein-rich concentrate mixture to keep them gaining steadily. The feeding of 200 to 300 lbs. of supplemental feed per head at that time saved 500 lbs. of concentrates and 400 to 500 lbs. of hay and other roughage needed later to make up the difference in weight and condition when the cattle were fattened for market.

286. Effect of rate of growth on length of life.—It is generally believed that the length of productive life is longer when an animal receives during growth a fairly liberal, well-balanced ration that permits rapid growth. The extensive experiments by Sherman and associates have been mentioned in the previous chapter, in which rats were fed a liberal ration containing an abundance of high-quality protein, of vitamins, and of calcium, in comparison with a more ordinary ration that produced normal growth. (**245**) The rats fed the superior ration not only grew faster than normal but also remained vigorous for a long time and had a greater length of life than those fed the ordinary ration.

In experiments by McCay and associates rats lived longer when they were raised on a diet that furnished ample protein, minerals, and vitamins, but which supplied so little energy that their growth was greatly retarded.[22] This lengthening of life was, however, due chiefly to a prolongation of the growth period and not to a longer adult life.

It is interesting that the rats which were underfed when young retained the capacity to grow at an age when growth has normally ceased. For example, rats were able to grow after they had been scantily fed to an age of 911 days, which is much more than their normal length of life. When underfeeding was continued as long as this, however, the animals never reached normal size.

Experiments mentioned in Chapter XXVII are being conducted to determine the effect of different levels of feeding of dairy heifers prior to first calving on their subsequent milk production, reproductive performance, and length of useful life.

287. Influence of soil upon breeds of livestock.—It is a common belief among those familiar with the livestock of various countries that the fertility of the soil in any district has a marked effect on the size and ruggedness of a breed of livestock which originates there.

Ashton, who studied this subject in Europe, concluded that the dwarf size of the Brittany breed of cattle in France was due largely to the great deficiency of calcium and phosphorus in the district where the breed was developed.[23] This dwarfed condition is apparently a result of the effect of the deficiencies through successive generations. Perhaps the animals of dwarf size could get along better on feed low in these minerals than animals with large skeletons, and thus survived while others perished.

Ashton concluded that, on the other hand, the large size and rugged frames of the Brown Swiss breed were due in part to the high calcium content of the soil in Switzerland. Also, for generations the cattle have secured their living from roughage, with little or no concentrates. This roughage has undoubtedly supplied a goodly amount of calcium, and of phosphorus as well.

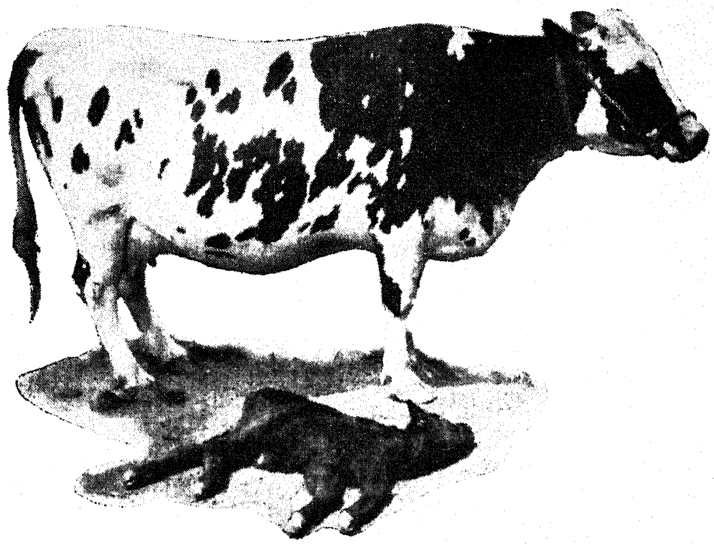
It was also pointed out that in the Island of Jersey the soil is more deficient in calcium and phosphorus than in Guernsey, where the cattle are larger. Breeders of the "Island type" of Jerseys in the United States recognize that there is a tendency for their cattle to become somewhat larger and more rugged in

bone when they are amply fed and kept on soil rich in minerals.

In a study in a good dairy section of New York where the cows were usually fed liberally, Misner determined the size of the cows in many herds and the amounts that were fed of various kinds of roughages.[24] He found that the cows averaged distinctly larger in size on the farms where a high proportion of the roughage was legume hay.

young. Without question, many of the failures in raising young stock are due to faulty nutrition of the breeding females. The sires must also be fed and cared for properly or their fertility will be low.

If the mother is fed inadequately, the offspring are apt to be weak or undersized at birth, and also the supply of milk may be scanty or of low vitamin content. Occasionally, the ration is so deficient that the young are born dead.



NUTRITIVE DEFICIENCIES CAUSE REPRODUCTIVE FAILURE

In Wisconsin experiments cows fed continuously on straw as the only roughage, plus grain and grain by-products, usually produced dead or weak calves. The reproductive failures were due chiefly to deficiencies of vitamin A and calcium. (From Wisconsin Station.)

The small size of the Shetland pony may be due in part to the rigorous climate of the Shetland Islands and the lack of fertility in the soil. In marked contrast are the Percheron, Belgian, Clydesdale, and Shire breeds of horses, all of which were developed in districts where the soil was rich and the climate was moderate.

IV. REPRODUCTION

288. Importance of adequate rations for breeding animals.—It is essential that breeding animals receive rations that fully meet the needs of their own bodies and also supply sufficient amounts of the various nutrients for the unborn

Fortunately, the mother is able to protect the unborn offspring to a certain extent against temporary or small deficiencies in her food by drawing on stores in her own body. Thus, she can draw on her skeleton for calcium and phosphorus and on her muscular tissues for protein. Such maternal protection is, however, at the expense of her own body.

The great differences that occur in reproductive efficiency of livestock is shown by a survey made by Phillips of the number of calves born on various western ranches per 100 cows in the herd at breeding time.[25] The percentage calf crop ranged from 40 to 77 per cent

in different sections of the western range area, with an average of 63 per cent. The calf crops on individual ranches ranged all the way from 25 to 95 per cent. While disease is often a very important factor in reproductive failure, undoubtedly the poor calf crops in some of these herds were due largely to nutritive deficiencies.

On account of the importance of the subject, especial attention is given in the chapters of Part III to the requirements during pregnancy of each kind of breeding stock. Rations, adapted to various parts of the country, are suggested there and in Appendix Table VII that should produce satisfactory results. Information is also given in Part III on the feeding, care, and management of sires of each class of stock. The requirements for egg production by poultry are discussed in Chapter XXXVI.

289. Nutrient requirements of females for reproduction.—It is especially important that the rations of pregnant animals furnish ample amounts of protein, minerals, and vitamins. These nutrients are particularly needed in the development of the unborn young, and deficiencies may produce serious effects.

While it is essential that mature pregnant animals receive a sufficient supply of these nutrients, the requirements during pregnancy are much less than for milk production. Also, most of the growth of the fetus is made during the last third of pregnancy. Until then it is not necessary to give a pregnant animal much more feed than would be needed to keep her in thrifty condition, if unbred. However, more care should be taken to provide sufficient protein, minerals, and vitamins. Pregnancy tends to make animals gain in weight and fatten more rapidly, because it makes them more quiet and also increases the appetite.

It is very important to feed pregnant animals more liberally during the last third of pregnancy. This is necessary to provide for the rapid growth of the fetus at this time and also to get the dam in condition to produce a good flow of milk.

In energy investigations with dairy heifers at the New Hampshire Station, Ritzman found that a month before calving, the amount of energy required by heifers was about 30 per cent higher than in nonpregnant heifers.[26] On the other hand, up to the fourth or fifth month of pregnancy, the energy requirement of pregnant animals was not appreciably higher than for those that were not pregnant.

It is shown later that the milk yield of dairy cows is considerably increased when they are well fed during the dry period. (1082) Also, their calves are more vigorous and the milk is richer in vitamin-A value. Similarly, it is shown in Chapter XXXI that when ewes are insufficiently fed during the last part of pregnancy, they are apt to have weak lambs. Also, they have insufficient milk for the lambs and may show but little motherly instinct.

In general, breeding females should be so fed that they are in thrifty condition. However, they should never be allowed to become too fat, or their breeding efficiency may be seriously decreased. Keeping them for long periods in over-fat, show condition is decidedly detrimental. Abundant exercise is essential for the best results.

It is important that breeding animals be raised well during the growth period. Undernutrition delays sexual development, and also females that have been poorly fed while growing are apt never to reach normal size. After they have their first offspring, the drain on their bodies in milk production prevents further growth unless they are fed liberally. Young pregnant females which have not yet completed their growth should therefore receive sufficient feed so they will be in good condition and of normal size when they have their first young.

290. Protein, minerals, and vitamins.—In comparison with the needs of a non-pregnant female, the requirement for protein during pregnancy is increased more than for total digestible nutrients or net energy. This is because the fetus consists chiefly of protein. The greatest need

for protein comes during the last third of pregnancy, when the growth of the fetus is most rapid.

The protein supply for pregnant animals should not only be sufficient in amount, but also the protein must be of proper quality. No attention need usually be given to the quality of protein in the case of dairy or beef cows, ewes, or mares, for the reasons that have been explained in Chapter V. (**112**) On the other hand, the quality of protein is as important as the amount of protein in feeding brood sows. Investigations with laboratory animals have shown that a lack of protein or a lack of one of the essential amino acids may cause a complete cessation of estrus, or heat periods.[27]

It has been shown in Chapter VI that a deficiency of minerals may cause reproductive disaster. Adequate amounts of calcium and phosphorus are necessary for successful reproduction. Also, attention must be given to the so-called trace elements, including iodine, iron, copper, and cobalt, in the areas where there may be a deficiency of one or more of these minerals.

A liberal supply of vitamin A, usually furnished by carotene, is especially necessary for pregnant animals. As is shown elsewhere, a lack of vitamin A will not only injure the unborn young, but will also cause the mother's milk and even the colostrum to be seriously deficient in the vitamin. (**192**) The vitamin A and carotene requirements of pregnant animals of the various kinds are therefore discussed in detail in Part III. The amounts of carotene advised for breeding females are stated in the Morrison feeding standards. (Appendix Table III.)

The requirements of the various animals for the other vitamins, including vitamins D, E, and C, and the B-complex vitamins, have been discussed in Chapter VII. Further information concerning any special needs by the different classes of stock is given in Part III.

291. Pasture and legume hay important for breeding stock.—Providing breeding stock with good pasture on fertile land during as much of the year as possible is the best insurance against nutritive deficiencies. Cows maintained continuously on well-balanced dry rations do not seem to reproduce so well as those allowed access to pasture.[28] Shy breeding, which develops on winter rations, is often overcome when the cattle have been on good pasture.

It has been mentioned previously that brood sows which are continuously kept in dry lot often have unsatisfactory litters or fail to nourish the pigs well after birth, even when the sows are fed apparently well-balanced rations. (**189**) The best substitute for pasture is alfalfa or other legume hay of first-class quality, but even this is not a complete substitute if the sows are raised in dry lot and continuously kept off pasture.

The importance of giving breeding stock plenty of good roughage, especially legume forage, is shown by the Indiana experiments with ewes which are reviewed in Chapter XXX. The results were unsatisfactory when breeding ewes were wintered on oat straw and corn silage for roughage, even when plenty of protein and mineral supplements were added. The deficiencies were corrected by furnishing excellent-quality alfalfa hay or dried immature grass.

292. Nutrients stored in the fetus.—The actual amounts of nutrients contained in a fetus at birth are not very large. The bodies of young animals at birth are very high in water content, new-born calves containing 71 to 75 per cent water. In Missouri experiments new-born 65-lb. Jersey calves contained about 11.8 lbs. protein, 2.5 lbs. fat, and 2.7 lbs. mineral matter; and 80-lb. Hereford calves, 14.6 lbs. protein, 2.9 lbs. fat, and 3.6 lbs. mineral matter.[29] These are no greater amounts of nutrients than are contained in 400 to 500 lbs. of milk of average composition. To these amounts of nutrients must be added those contained in the fetal membranes and fluids.

These data show why pregnant animals do not require such great amounts of nutrients, even during the last part of pregnancy, as are needed for producing a good yield of milk.

293. Nutritive requirements of sires.—Practical experience shows that sires must be kept in thrifty condition to retain their breeding powers. Care must therefore be taken to make sure that their needs for protein, minerals, and vitamins are met. However, the nutrient requirements for mature sires in ordinary service are not far different from the needs for mere thrifty maintenance. Information is given in Part III on the feeding and care of sires of each class of stock.

It will be noted in the experiments there summarized that a nutritive deficiency, as of vitamin A, usually produces visible symptoms of deficiency in the sire, before it impairs his breeding potency.

Young sires should be fed so that they grow normally and develop vigorous bodies and strong skeletons. They therefore need rations having ample amounts of protein, minerals, and vitamins.

QUESTIONS

1. Why is thrifty growth important in farm animals?
2. Compare the nutritive requirements for growth and for maintenance, considering: (a) Protein; (b) total digestible nutrients; (c) minerals; (d) vitamins.
3. How can the amounts of protein required by growing animals be determined?
4. Which is more serious for a young animal—a moderate deficiency of total digestible nutrients or a lack of an essential mineral or vitamin?
5. How can one be sure that calves, lambs, and foals have plenty of calcium, without feeding a special calcium supplement?
6. Which vitamins are most apt to be lacking in the rations of pigs in winter?
7. Discuss the utilization of food by young animals. Why do young animals produce meat more economically than older ones?
8. What is the relative rate of growth of different parts of the body at various ages?
9. State 7 nutritive virtues of whole milk for young animals.
10. What deficiencies does milk have as an exclusive food over long periods?
11. Why should a very young animal not be fed milk unduly rich in fat?
12. Why is it important that new-born animals receive the colostrum?
13. What is the object of fattening meat animals?
14. Discuss the composition of the gains made during fattening.
15. Why is it generally uneconomical to carry an animal to a greater degree of fatness than is necessary to meet the market demands?
16. From what nutrients may body fat be formed? From what source is most of it usually made by farm animals?
17. What is the effect of food fat upon body fat in swine and in ruminants?
18. Discuss the requirements of fattening animals for the following: (a) Total digestible nutrients or net energy; (b) protein; (c) minerals; (d) vitamins.
19. What factors, other than the ration, influence the rapidity and economy of gains during fattening?
20. What is the effect of feeding young pigs such a ration as corn alone?
21. What method of feeding produced the best bacon carcasses in the English experiments?
22. Of what practical importance are the results of the experiments in which growing animals have been fed scanty rations for a time?
23. What results were secured when beef calves were fed enough supplemental feed, in addition to dried-up range, to keep them growing steadily?
24. What is the effect of nutrition upon length of life of rats?
25. How may the fertility of the soil in a region affect the size of farm animals?
26. Discuss the importance of adequate rations for breeding animals.
27. Compare the nutrient requirements for pregnancy with those for milk production.
28. Discuss the importance of pasture and legume hay for breeding stock.

CHAPTER X

PRODUCTION OF MILK, WORK, AND WOOL

I. Production of Milk

294. The secretion of milk.—For good growth of all young mammals an abundant supply of the mother's milk is necessary under normal conditions. It is therefore essential that we understand the main facts concerning the requirements for the secretion of milk.[1]

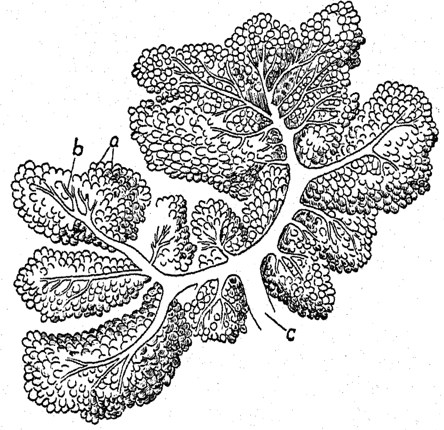
The fully developed mammary gland, in which milk is secreted, consists of a multitude of small, sac-like secreting bodies (called alveoli) and the duct system into which the milk is poured. The alveoli are grouped into clusters, much like bunches of grapes.

The smallest ducts, into which the alveoli secrete the milk, unite to form larger ones. The ducts are not uniform in size throughout their length but are greatly enlarged in places, to provide more storage capacity for the milk as it is secreted. In some animals the large milk ducts open directly on the surface of the teat, but in others, as in cows, they open into a small cavity, called the milk cistern, which is just above the teat.

The amount of milk an animal can produce depends primarily on the amount of secreting tissue in the mammary glands. In good dairy cows, for example, not only is the udder large, but most of it consists of actual secreting tissue.[2] On the other hand, in the udders of beef cows there is much less secreting tissue, and a considerable part of the udder consists of fatty tissue.

When milk is secreted, the blood, laden with nutrients, is brought by the capillaries of the udder to the alveoli. The nutrients then pass through the walls of the capillaries into the lymph and thence into the cells of the alveoli. Here, by one of nature's wonderful processes they are converted into milk, that differs greatly in composition from the blood from which it is made.

Only a very small portion of the nutrients in the blood is removed each time the blood passes through the udder. Therefore the rate of flow of blood is truly remarkable in the case of a high-producing cow. It is estimated that about 400 lbs. of blood flow through the udder for each pound of milk produced.[3] Thus, in the case of a cow yielding 60 lbs. of milk a day, 24,000 lbs. of blood would flow through the udder in a day.



Portion of Mammary Gland of Cow

Small portion of gland, greatly magnified. A, alveoli, in which milk is secreted; b, small milk duct; c, larger milk duct. (After Klein.)

The great number of times the blood makes the circuit from the heart to the udder and back again is evident from the fact that this amount of blood is about 300 times the total amount of blood in the body of a 1,000-lb. cow. The energy required to pump this amount of blood through the udder represents only a small part of the requirements of the cow for milk production. There is therefore no question but that

a good cow is a very hard-working animal.

295. Source of nutrients in milk.—The chief constituents of milk—casein, milk fat, and lactose (milk sugar)—are true secretions of the mammary gland, for they have special properties and are found nowhere else in the body. Certain constituents of milk are transferred direct from the blood, including mineral matter, the vitamins, globulin, and albumin.

Investigators have endeavored to determine the exact blood source of the various nutrients in milk.[4] One method has been to analyze samples of blood taken from an artery of a cow before it passes through the udder and of blood from a vein after passage through the udder. In some of the studies various nutrients labeled with radio-isotopes have been used in order to trace the origin of the milk constituents.

The experiments indicate that casein is made chiefly from amino acids taken up from the blood. Some synthesis of certain amino acids for making the casein may occur in the mammary gland. The milk fat is mostly derived from the fat of the blood. In the case of ruminants, but not in non-ruminants, the simpler fatty acids may be formed from acetic acid produced in the bacterial carbohydrate digestion in the rumen. The lactose is formed principally from blood glucose.

296. When is milk secreted?—Investigations have shown that milk secretion is a continuous process and that most of the milk obtained at a milking is already present in the udder when milking begins.[5] For example, when cows have been slaughtered just before the normal milking time and their udders removed, the udders have contained nearly as much milk as was secured at the previous milking.

The rate of secretion is probably most rapid for a time after milking is completed, for there is then little or no pressure in the udder. As the milk gradually accumulates in the milk ducts before the time of the next milking, the rate of secretion tends to slow up, due to the increasing pressure. When the pressure becomes great enough, secretion entirely ceases. This is why cows can be dried off by abrupt stopping of milking. (**1081**)

297. "Letting down" and "holding up" of milk.—The secretion of milk is involuntary and cannot be prevented by the animal, any more than can breathing or the circulation of the blood. The yield may, however, be reduced considerably through nervousness caused by fright or unusual conditions.

It is explained in Chapter XXVI that if the proper stimulus occurs at milking time, the milk is forced out of the alveoli and small ducts of the udder by the action of a hormone produced in the pituitary gland at the base of the brain. (**1093**) We then say that the cow has "let down" her milk.

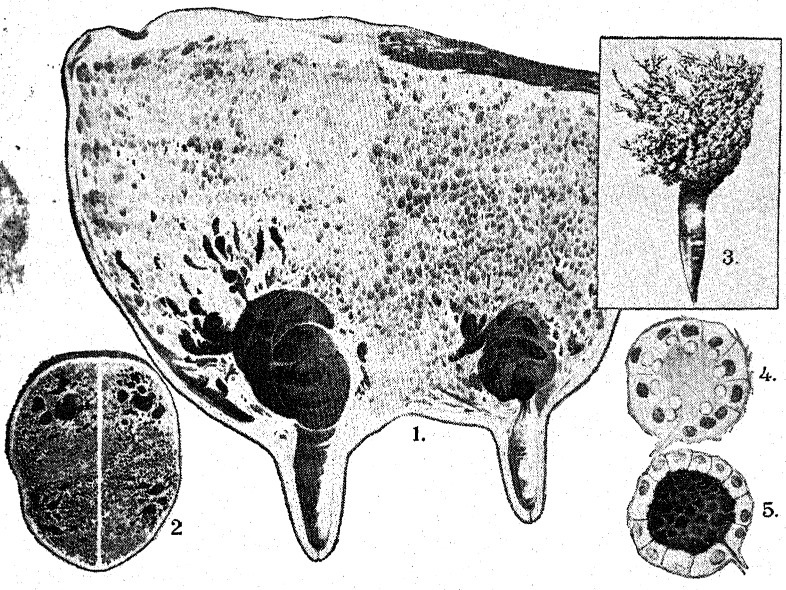
If she does not receive the proper stimulus, this hormone is not secreted, and we say that she "holds up" her milk, because it is not forced out of the alveoli and ducts. More milk is secured by rapid milking than by slow milking, because the effect of the hormone lasts only a short time.

These studies provide an interesting explanation for the well-known fact that regularity in feeding and stable management is necessary to secure the largest yields from good cows. Also, the kind milker who gains the confidence of cows secures more milk from them than a rough or indifferent person.

298. Development of the mammary glands.—The mammary glands of a young female are only slightly developed before sexual maturity, but then develop through the action of certain hormones.[1] For example, in the case of dairy calves, the milk ducts leading out from the milk cistern are small and short, with few branches. After sexual maturity is reached and the animal comes in heat, the duct system begins to grow and branch out into the fatty pad of tissue which at that time composes most of the udder. This growth is caused by a hormone which is secreted in the ovaries and carried in the blood to the udder. This hormone, usually called *estrogen*,

or *estradiol,* is the same hormone that causes the heat period in females. With the successive heat periods, further growth of the duct system occurs.

If the animal does not become pregnant, the duct system becomes fairly extensive, but there is not much development of the alveoli, which are the secreting tissues. When pregnancy occurs, a further growth takes place in the duct system, and also the alveoli develop rapidly. This is caused by estrogen and also by a hormone secreted by the corpus luteum, or "yellow body," in the ovary of the pregnant animal. This hormone is usually called *progesterone.* Hormones produced by the pituitary gland also seem to be concerned with the growth and development of the mammary glands.



STRUCTURE OF THE COW'S UDDER

1. Longitudinal section through one side of udder and teats of cow. The narrow duct at the end of the teat, or the teat canal, may be seen, also the cavity in the teat, and the milk cistern. Although there is no septum, or visible division, between the fore and hind quarters, no communication exists between the milk ducts in the two quarters. In this section the tissue of the fore quarter is colored slightly lighter than that of the hind quarter.

2. Horizonal section of the four quarters of the cow's udder. The septum, or division, between the right and left halves of the udder is clearly visible. Note the size and distribution of the milk ducts.

3. Milk cistern and milk ducts of a fore quarter of udder.

4. Cross-section of an alveolus before milking. The droplets of fat, indicated in the figure by the light-colored spots in the cells, are discharged into the cavity of the alveolus through the cell walls when milk is secreted.

5. Cross-section of an alveolus after milking. This should be contrasted with Figure 4, as it shows the appearance of the cells of the alveolus following secretion. Note that the cells have lost their fat droplets and their fluid to a large degree. (Reproduced from charts by Rubeli, Berne, Switzerland.)

In some animals the growth of the secreting tissue is largely completed during the first half or two-thirds of pregnancy. The cells of the alveoli then begin to secrete a fluid that resembles colostrum, which is the first milk yielded by the mother after the birth of the young. The beginning of secretion is brought

about, not by either of the two hormones that have been mentioned, but by a hormone called *prolactin,* or *lactogen,* which is secreted by the forward, or anterior, part of the pituitary gland.[6]

Because of the rapid enlargement of the udder during the latter part of pregnancy, it was formerly thought that nearly all the growth of the gland takes place at that time. However, much of the increase in size is due to accumulation of secretion in the alveoli and ducts.

The function of the colostrum in protecting the new-born against disease has been explained in the previous chapter. (**270**)

When the milk yield decreases during the latter part of the lactation period and the animal finally "goes dry," the alveoli disappear to some extent and are rebuilt during the next pregnancy period.

Young heifers often develop the habit of sucking each other, and this manipulation of the udder will sometimes start the secretion of milk, even in the unbred animal. In one instance at the Wisconsin Station a barren heifer produced over 5,000 lbs. of milk in 630 days, the maximum daily yield being 18.7 lbs.[7]

Such a milk flow is, however, much less than the animal would produce following pregnancy and the birth of young.

299. Use of hormones to cause milk production.—Experiments have shown that udder development and secretion of normal milk can be produced in non-pregnant females by the hypodermic injection of hormones, or implanting a tablet of the hormone under the skin. This effect is produced not only by natural hormones, but also by certain synthetic compounds, especially diethylstilbestrol.

Experiments have been conducted with heifers and cows that failed to conceive, to find whether treatment with hormones would produce worth-while milk yields.[8] In some cases yields of as much as 431 lbs. of fat in 10 months have been secured, but in other instances the results have been disappointing. The effect has seemed to be more favorable with heifers than with cows.

300. Milk production requires large amounts of nutrients.—Many do not realize fully the large amounts of nutrients that are yielded by an animal producing a good flow of milk, and that must therefore be supplied in her feed. A fair cow yielding annually 8,000 lbs. of milk containing 3.5 per cent fat will produce in her milk each year much more protein and somewhat more energy and minerals than there are in the entire body of a fat 2-year-old steer. In addition, she will have developed the body of her calf.

Unless an animal in milk receives sufficient nutrients to meet her needs, she cannot continue to produce a good yield. During the first part of the lactation period, if the animal is fed insufficiently she will do her best to provide enough milk for her young by drawing nutrients from her body. However, this cannot continue long, and her milk yield will fall to the amount that can be made from the nutrients she receives.

Since milk is especially rich in protein and also in calcium and phosphorus, the ration of an animal producing milk must supply liberal amounts of these nutrients. Also, the protein in the ration must be of satisfactory quality, as has been shown in Chapter V. The large requirements for protein, total digestible nutrients, calcium, and phosphorus for milk production are in strong contrast to the amounts needed by an animal that is merely being maintained, or even by a pregnant animal that is not producing milk.

The quantities of the various nutrients required by any milking animal will depend primarily on the amount of milk that is actually being produced. Thus, a cow yielding 60 lbs. of milk a day will need twice as much nutrients, above her maintenance requirements, as will one producing only 30 lbs. of milk of the same richness. Also, a greater amount of nutrients is required for each pound of rich milk than for milk low in fat percentage.

These simple facts are disregarded by many dairymen, who allow the net returns from their herds to be seriously

reduced because they do not feed the individual cows in proportion to their actual productions. This important matter is discussed in Chapter XXV.

In considering the food requirements for milk production it should be borne in mind that the mammary gland does not receive a particular kind of blood suited to its special needs. It receives the very same kind of blood that flows to the other body tissues, and therefore it must compete with the other organs for its supply of nutrients.

The requirements for milk production by the various farm animals are discussed in detail in the chapters of Part III, and example rations for each class of stock are given in Appendix Table VII. The amounts of nutrients advised for each kind of milking animals are stated in the Morrison feeding standards. (Appendix Table III.)

301. Protein.—Often the milk production of farm animals is lowered by a lack of sufficient protein in the ration. Care should therefore always be taken to provide ample protein. In the case of brood sows, attention must be given to the quality of protein, as well as to the amount. For the reasons explained in Chapter V, the quality of protein in any usual ration for dairy cows, beef cows, ewes, or mares will generally be satisfactory, if good quality roughage is fed. (112, 127) If considerable of the roughage is legume forage, satisfactory quality of protein in the ration is insured.

Protein is used very efficiently in milk production, especially by good dairy cows. This is shown by the fact that fairly good production is secured when cows receive in their feed, in addition to their maintenance requirements, only 1.25 lbs. of digestible protein for each pound of protein in the milk. In the economy with which she converts the protein of feeding stuffs into protein of the highest nutritive value, the dairy cow far excels the other farm animals, as is emphasized in Chapter XII. (351–352)

302. Total digestible nutrients or net energy.—The requirements for total digestible nutrients and net energy in milk production are far greater than the needs for pregnancy, even during the last months, when the growth of the fetus is most rapid. The high need for energy in milk production is shown by the fact that the metabolic rate of the body is so speeded up in producing a good yield of milk that twice as much heat is produced as in animals that are not lactating.[9]

For efficient milk production, dairy cows, beef cows, brood mares, and breeding ewes should, first of all, receive a liberal supply of good-quality roughage. This will not only furnish total digestible nutrients and net energy, but it is also important in providing minerals and vitamins. In addition to roughage, they should receive whatever amounts of concentrates are necessary to maintain a satisfactory flow of milk. Brood sows must get most of their nutrients for milk production from concentrates.

The amount of concentrates required for any class of stock depends on the quality of the roughage they receive and on the amount of milk they are yielding. Thus, beef cows nursing calves need no grain in addition to good pasture, while high-producing dairy cows cannot secure enough nutrients from pasture alone, unless it is most excellent.

303. Fat requirements.—Investigations have shown clearly that the fat in milk can be formed not only from the fat in the feed but also from carbohydrates and even indirectly from protein. For example, in an experiment many years ago by Jordan and associates a cow was fed for over 3 months a ration from which nearly all the fat had been extracted.[10] During the trial she produced 62.9 lbs. of fat in her milk, while there was only 5.7 lbs. of digestible fat in her feed. The rest was made chiefly from carbohydrates, as but relatively little could have come from excess protein in the ration.

In spite of the fact that the fat in milk can be made from other nutrients than fat, a certain minimum amount of fat is needed in the ration for maximum milk yield, at least with high-producing dairy cows and milk goats. Extensive ex-

periments summarized in Chapter XXV showed that when good dairy cows were fed concentrate mixtures having only 2.7 per cent fat, with the usual roughages, they produced 4 per cent less milk than when the ration had more fat. (1020) The difference in yield, which was only small, could be made up by feeding a slightly larger amount of the low-fat concentrate mixtures.

The effect of the low-fat ration may have been due to the less efficient use of energy on a ration very low in fat, which has been mentioned previously. (133) Another possible explanation is that cows are able to make milk fat more readily from food fat, though they can synthesize it from other nutrients.

In these experiments the percentage of fat in the milk was not appreciably reduced on the low-fat rations in the case of dairy cows, but the milk yield was slightly less. However, with milk goats a ration very low in fat tended to decrease the fat content of the milk.

So far as is known, no especial attention need be paid to the fat content of rations for beef cows, ewes of the common breeds, brood mares, and brood sows. This is because their milk yield is not large in comparison with that of high-producing cows or milk goats.

304. Mineral and vitamin requirements.—The mineral and vitamin requirements of farm animals have been discussed at some length in previous chapters. The importance was there emphasized of supplying sufficient calcium, phosphorus, vitamin A, and vitamin D to make possible a high yield of milk, without injury to the animal.

The mineral and vitamin requirements for milk production by the various classes of stock are considered further in Part III, and the influence of the vitamin supply in the ration upon the vitamin content of the milk is discussed later in this chapter.

305. Effect of various factors upon the composition of milk.—The effects of various factors upon the yield and composition of milk have been studied chiefly in experiments with dairy cows. These factors are therefore discussed in detail in Chapter XXV.

In general, there is a strong tendency for a lactating animal to produce milk of normal composition under widely varying conditions. Any inadequacy in the ration or fault in the methods of care and management will generally manifest itself by a reduction in the yield of milk, rather than by a change in its chemical composition. However, certain factors have an effect on the fat percentage. The content of certain trace minerals in milk can be increased by a very liberal amount in the feed. A very important fact is that the vitamin A value of the milk depends on the vitamin A or carotene content of the ration.

306. Effect of feed on protein, fat, and milk sugar of milk.—A deficiency or an excess of protein in the ration does not appreciably change the composition of milk. However, a lack of protein greatly decreases the yield. In Ohio experiments cows fed rations unusually lacking in protein produced a low yield, but the milk did not differ in any important respect from that of cows fed rations rich in protein.[11] Calves and laboratory test animals made equally good growth on the two kinds of milk. The only significant difference was that the milk from the high-protein feeding contained more of the non-protein nitrogenous compounds, including urea, which are found in traces in milk. Also, this milk was slightly higher in the vitamin B complex.

If the ration of a dairy cow does not have a certain minimum amount of fat, the yield of milk will be reduced, as has already been mentioned in this chapter. The experiments reviewed in Chapter XXV show that the richness of the milk may be considerably increased for a few days by adding fat or fat-rich feeds to the ration. The fat content, however, tends to fall back to normal later, even though the feeding of fat is continued. Certain feeds, especially coconut meal and palm-kernel oil meal, may cause a very slight increase in the fat content of milk over a longer period. On the other hand, cod-liver oil and certain other fish

oils decidedly decrease the percentage of fat in the milk of cows.

When fed in considerable amounts, feeds that are rich in fat may have a marked effect on the character of the fat in milk, just as they do upon the body fat produced by swine. Thus, soybeans and peanuts tend to produce soft butter, while cottonseed meal and coconut oil meal make hard butter with a high melting point.

The percentage of lactose in milk cannot be changed by any ordinary method.[12]

307. Effect of feed on minerals in milk.—The percentages of the principal minerals in milk are not changed to any appreciable extent by the amount of these minerals in the feed. In a recent Ohio study the content of calcium, phosphorus, and certain other minerals in the milk produced by cows on improved legume pasture did not differ from that in the milk of cows on permanent bluegrass pasture.[13] Though a ration seriously deficient in phosphorus or calcium will reduce milk production and may cause serious injury to the animal, the milk that is produced will have about the normal content of these minerals.[14]

Milk is very low in iron, as has been stated before. It is apparently impossible to increase the amount by increasing the supply in the feed.[15] (174)

The amount of iodine and the amount of cobalt in cow's milk can be increased decidedly by adding to the ration a supplement supplying the mineral.[16] However, the cow is very inefficient in transferring iodine into her milk.

It has occasionally been advocated that iodine should be added to the rations of dairy cows so that their milk might be used as a goiter preventive for humans in iodine-deficient districts. Most medical authorities agree that the production of such "iodized" milk is inadvisable and unnecessary. The use by humans of iodized salt as insurance against goiter is much cheaper, and the dosage of iodine in this form can be much more easily standardized.

In spite of certain advertising claims to the contrary, the addition of iodine supplements to the rations of dairy cows in careful experiments has not been beneficial in regions where there is no deficiency of iodine in the soil or water. (171) Adding too much iodine to a ration is definitely injurious.

It is of scientific interest, but not generally of any practical importance in stock feeding that the very small amounts in milk of certain other minerals—manganese, zinc, copper, molybdenum, and boron—can be changed somewhat by the supply in the feed.[17]

308. Effect of feed on the vitamin content of milk.—The effect of the ration upon the vitamin content of milk has been considered in the discussions of the various vitamins in Chapter VII. It is emphasized there that the vitamin A value of milk depends on the carotene or vitamin A content of the feed. While milk will be rich in vitamin A if produced by an animal fed a ration having plenty of vitamin A value, the amount of the vitamin will be low if the ration is low in this nutritive essential.

The vitamin A value of milk is of great importance, not only from the standpoint of the value of milk for humans, but also in raising livestock. Information is therefore given in Chapter XXV concerning the vitamin A value of milk produced by cows under various conditions. (1044)

It has been explained in Chapter VII that the vitamin D content of milk is not high from cows fed any ordinary rations. Any considerable increase can be made only by feeding cows large doses of vitamin D in such a form as irradiated yeast.

The content of B-complex vitamins in the milk of non-ruminants is affected considerably by the amounts of these vitamins in their rations. These vitamins are synthesized in the bacterial fermentations occurring in the rumen of ruminants. Therefore ruminants do not require them in their feed, and the content in their milk does not depend chiefly on the amounts in their rations.

The thiamine content of milk is rather low, and the content in cow's milk cannot apparently be increased by feed-

ing yeast or other feeds rich in the vitamin.[18] The amount of riboflavin is somewhat higher when the ration includes a liberal supply of feeds rich in the vitamin, such as green pasturage or other green forage.[19]

Milk contains but little vitamin C, and it is apparently impossible to increase the vitamin C content of cow's milk by the use of feeds rich in the vitamin.[20]

II. The Production of Work

309. The source of muscular energy.—Carbohydrates are the primary and the most efficient source of energy for muscular work. However, fat and protein can also be used indirectly, probably through previous formation of carbohydrates from these nutrients. Under normal conditions, the carbohydrates and the fat of food are first used, and little more or no more protein is broken down than during rest. Should the carbohydrates and fats of the food not furnish enough energy, the body fat is next used. Finally, as a last resort, the muscles or other protein tissues can be called upon, if the energy can be secured from no other source.

Since the greater part of the food of farm animals consists of carbohydrates, most of their muscular energy undoubtedly comes from this source. Also, carbohydrates are apparently the most efficient source of energy for the production of work.

310. Production of muscular work.—We know that in doing work the muscles of the body contract; that is, become shorter and thicker. However, there is still some question as to the manner in which the energy of the food nutrients is converted into muscular movements. Yet some of the processes that take place are definitely known.

In muscular work the glycogen, or animal starch, which has been stored in the muscles during rest, is used up. Increased amounts of oxygen are taken up from the blood, and the amount of carbon dioxide produced in the body is increased in proportion to the amount of work done. Part of the energy in the nutrients used up in the muscular contractions is changed into the mechanical work produced, while part is set free as heat. This latter part is waste energy.

During rest, glycogen is stored in the muscles, forming from 0.5 to 0.9 per cent of the weight of well-nourished muscle when resting. A smaller amount of glucose is also stored in the muscles. During muscular activity, the stored glycogen is used up in proportion to the severity and duration of the work, and after prolonged hard work the supply may be entirely exhausted. Though the amount of glycogen in the muscular tissues at any one time is small, it is replenished from the supply of glucose that is continuously brought to them in the blood.

Physiologists have conducted painstaking experiments in an endeavor to determine the chemical processes that occur in muscular contraction. However, opinions still differ as to the exact reactions which occur. The theory most commonly accepted is that muscular contraction is not caused by energy furnished directly by the oxidation of glycogen or other nutrients.[21] Instead, the energy needed for the contraction apparently comes from the sudden break down of an organic phosphorus compound in the muscle. In this part of the process no oxygen is used up. Another organic phosphorus compound also seems to be involved in the process.

During the relaxation of the muscle, these organic phosphorus compounds are formed again. The necessary energy for their formation is furnished by a conversion of glycogen into an organic acid (lactic acid or pyruvic acid) and oxidation of the organic acid to carbon dioxide and water.

The first part of the process in muscular contraction is therefore somewhat similar to the release of energy by a storage battery. It is not like the production of mechanical energy by a steam engine, where the fuel is burned (oxidized) before the work is performed. The oxidation of nutrients in work occurs *after* the muscular contraction, in the recovery phase of the process.

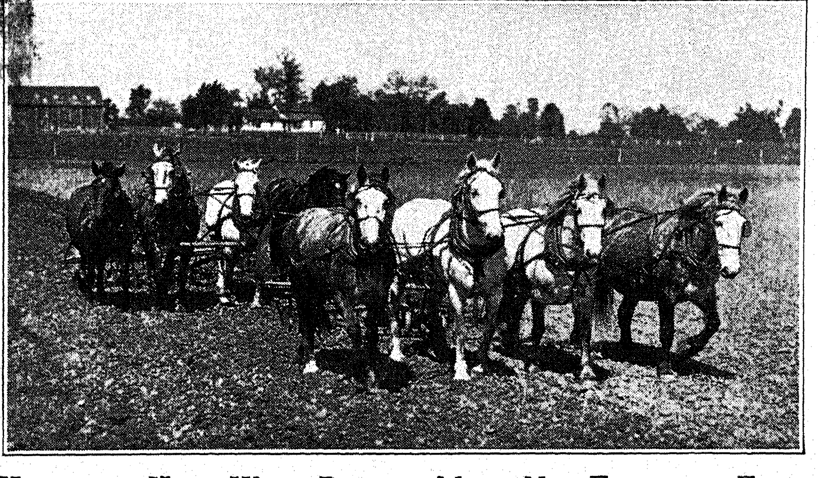
It is for this reason that an animal can perform for a few minutes several times the normal amount of work. For example, a man can temporarily do mechanical work at the rate of a full horse power. This requires several times as much energy as could be liberated by the direct oxidation of nutrients with all the air a man can possibly breathe in per minute.

311. Nutrient requirements for work animals.—The chief need in rations for work animals is a sufficient supply of feeds rich in total digestible nutrients or net energy. A mature animal needs during work but little more protein, minerals, and vitamins than are required for satisfactory maintenance at rest. The requirements for work therefore differ greatly from those for growth, for milk production, or for wool production.

A young work animal that is still growing needs more feed than a mature animal doing the same work. Also, the requirements of a brood mare are increased during pregnancy and especially when suckling her foal. It is important that both these classes of work animals have plentiful supplies of protein, minerals, and vitamins.

The value of any particular feed for work production depends on the amount of net energy it yields. This is because the energy used up in the heat increment, or so-called work of digestion, is all converted into heat, and is wasted so far as the production of work or the formation of body tissues is concerned. (68)

The amounts of digestible nutrients or net energy that are required for any particular work animal will depend on the amount of labor performed. Accordingly, the proportion of concentrates in the ration must be increased as the work becomes harder. For severe work, horses and mules must be fed a liberal amount of such concentrates as the farm grains. On the other hand, animals doing light work can be fed mostly on roughage.



HORSES AT HARD WORK REQUIRE MUCH NET ENERGY IN FEED

On account of the large amount of energy they expend in the work they perform, horses at hard work must receive a liberal amount of concentrates high in net energy.

Many investigations have been conducted to find whether there is any increase in the amount of protein broken down in the body during work, provided there are abundant supplies of carbohydrates and fat. Opinions on this question still differ, but it is agreed, at least, that even during hard work there is no marked increase in the amount of protein used in the body, if the amounts of other nutrients are ample.

For this reason, a mature animal

needs during work but little more protein than is required for satisfactory maintenance at rest. However, as has been shown in Chapter IV, the digestibility of a ration is usually decreased when the proportion of protein is too low. Also, it is believed that a supply of protein somewhat above the minimum requirements tends to give work animals better life and spirit. These factors have been taken into consideration in the recommendations made in the Morrison feeding standards. (Appendix Table III.)

The mature animal when at work does not need a much greater amount of minerals or vitamins than when merely being maintained at rest. However, since a long life of usefulness is important, it is wise to be sure that there is a plentiful supply of these nutrients in the ration.

Detailed discussions of the nutrient requirements of work horses and mules are given in Chapter XXXII. Typical rations which are adapted to various sections of the country are recommended in Appendix Table VII for idle animals and for those performing light, medium, and hard work.

312. Efficiency of the animal as a machine.—It is shown in Chapter XXXII that when horses work at the usual rates they convert into the actual work produced, about 20 to 25 per cent of the energy they expend during the time they are working. The rest of the energy is wasted in the form of heat.

These figures do not take into account the energy lost in the undigested part of the feed and the energy used in maintaining the body when the horse is not working. Allowing for these, a horse doing a full day's work will turn about 9 per cent of the total energy in the feed it eats into actual useful work, such as hauling a load. This efficiency is not far below that of the best gasoline tractors.

The efficiency of the animal is especially striking when it is remembered that the tractor is supplied with purified fuel (kerosene or gasoline) while the horse must secure its energy from crude materials, including hay of which only about half is actually digestible. Furthermore, he must digest his feed and separate the useful from the waste material. Also, he must make all body repairs. Last, but not least, he must maintain his body during the part of the 24 hours that he is not working, while all expenditures of energy cease when the tractor stops work.

313. Factors influencing energy required for work.—The amount of energy required to produce a given amount of useful work depends upon many factors. Practice in doing a certain kind of work lessens the amount of energy expended.

On the other hand, fatigue greatly increases the energy required to do a task. This is largely due to the fact that with increasing fatigue the muscles normally used, and which are thus most efficient in performing the given work, are put out of use by the exhaustion of nutrient reserves or the accumulation of waste products. Then other less efficient muscles are called upon to a constantly increasing degree, and these cannot perform the work so economically.

Increasing the speed at which the work is done also lessens the efficiency with which it is performed. This is because the work of the heart is increased, the body temperature rises, and much heat is lost by the evaporation of water through the skin and lungs. This decreases the amount of work that a given quantity of feed will produce. Furthermore, when a horse trots or gallops, the rise and fall of the body is much greater than in walking, and therefore it has available for onward movement less of the total energy that is expended.

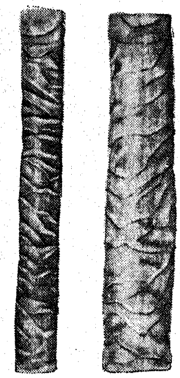
The portion of the expended energy which is converted into useful work varies with the build of the animal, the development of its muscles, and the structure of its limbs. For example, a lame horse may use nearly twice as much energy in traveling a certain distance as one with sound legs. An animal which is able to perform one kind of work most economically may have to expend undue energy at other kinds of work. Thus, horses bred for generations to the saddle can carry the rider with a smaller expenditure of energy than those whose

breeding and form specially fit them for draft purposes.

Additional discussions of the factors influencing the production of work, as applied to horses, are given in Chapter XXXII.

III. Wool Production

314. Composition of wool.—Wool fibers are practically pure protein and are of the same chemical composition as hair, but they differ from hair in being covered with minute overlapping scales.



Wool Fibers

Appearance of fibers, greatly magnified, after dirt and yolk have been removed. Left, fiber of Merino wool; right, fiber of Down wool. Note the overlapping scales covering the fibers.

These give wool its characteristic valuable properties as a textile. In addition to the wool fibers, raw wool contains a large proportion of adhering material which must be removed by scouring before the wool is manufactured into cloth.

Most raw wool shrinks 50 to 65 per cent on being scoured. In other words, only 35 to 50 lbs. of dry, clean wool fiber are secured from each 100 lbs. of raw wool. The shrinkage is made up of wool grease, suint, dirt, adhering chaff or other plant material, and moisture. The value of a fleece of wool depends first of all on the weight of clean, scoured wool it will yield, and then on the nature and quality of the wool fiber.

The shrinkage is greater for fine wool than for coarser wool, as fine wool contains much more grease. It is usually higher for wool from range sheep than from those kept under farm conditions, as the range wool usually carries more dirt and extraneous material.

The wool grease is important in protecting the fiber from injury by the weather. It is largely made up of combinations of cholesterol with fatty acids, and is therefore not a true fat. The suint is chiefly composed of potassium salts of various fatty acids. As it is soluble in water, there is less in sheep exposed to the weather. The term "yolk" is applied to the wool grease and suint combined, and sometimes to the wool grease alone.

315. Requirements for wool production.—Because of the wool they produce, sheep need a somewhat larger supply of protein and also of total digestible nutrients than do cattle or swine at the same stage of maturity. This is taken into consideration in the feeding standards for the various classes of sheep. (Appendix Table III.) For growing lambs, pregnant ewes, and ewes suckling lambs, there is a double need for protein. The nutrient needs of sheep and lambs are discussed in detail in Chapters XXX and XXXI.

The mohair produced by Angora goats has the same general chemical composition as wool fiber, though differing in structure. Therefore the nutrient requirements of these goats are similar to the requirements of sheep. The requirements of milk goats, on the other hand, resemble those of dairy cows.

Sickness, undue exposure, or a decided lack of feed will decrease the yield of wool, will produce smaller and weaker fibers, and will sometimes even cause weak spots in the fibers.[22] Wool that has a weak spot is said to have a "break" or to be "tender." Unless the undernutrition is severe, the amount of yolk (wool grease plus suint) will be decreased more than the yield of scoured wool.

In a California trial sheep produced more than three times as much scoured wool when fed a liberal fattening ration for 6 months as when poor-quality alfalfa hay was fed in amounts not quite sufficient to maintain their weights.[23] The

wool fibers were only half as strong on the sub-maintenance ration, and they were seriously lacking in crimp. In a Nebraska trial lambs fed a liberal ration for about a year produced more than twice as much scoured wool as others given slightly less than a maintenance ration.[24] The wool fibers produced on the scanty ration were shorter and much smaller in diameter.

Exposure and insufficient feed, such as sheep are often subjected to under range conditions during the winter, will considerably reduce the yield of scoured wool, in comparison with the yield under better conditions of feeding and shelter.[25] Louisiana experiments show that serious underfeeding of sheep may even cause shedding of the wool, which sometimes occurs in sheep, even when not infected with scab.[26]

If lambs are fed so that they make rapid gains, they will have larger bodies at a given age and be more mature than if fed somewhat less liberally. They will consequently shear heavier fleeces.

In most of the tests that have been reported, ewes have had heavier fleeces at 2 to 3 years of age than as yearlings.[27] Rambouillets reach maximum fleece weights somewhat later than the mutton breeds. After 3 to 4 years the fleece weight gradually declines with increasing age. In Texas studies the diameter of the wool fibers of Rambouillet sheep remained relatively constant throughout the useful life of the sheep. The length of the fibers was greatest the first year and declined after the fourth year.[28] Ewes producing lambs yielded slightly less wool than did ewes that had no lambs, and their wool was a trifle shorter.

QUESTIONS

1. Describe the structure of the udder, and tell what is known about the manner in which milk is secreted.
2. What is probably the source of the following constituents of milk: (a) Protein; (b) fat; (c) lactose?
3. When is milk secreted?
4. Describe the development of the mammary gland after the animal reaches sexual maturity; after pregnancy occurs.
5. Discuss the use of hormones to cause milk production.
6. Compare the nutrient requirements of a lactating animal with the requirements for maintaining a mature animal. Consider protein, minerals, vitamins, and total digestible nutrients or net energy in your discussion.
7. Discuss the protein requirements for milk production. About how much digestible protein does a dairy cow require in her feed, in addition to the maintenance requirement, for each pound of protein she produces in her milk?
8. Discuss the total digestible nutrient or net energy requirements for milk production.
9. From what food sources can the fat in milk be formed? Of what importance is the percentage of fat in a concentrate mixture for dairy cows?
10. To what extent can the composition of milk be changed by the feed an animal receives? Consider: (a) Protein; (b) percentage and character of fat; (c) lactose; (d) minerals; (e) vitamin A value.
11. From what food nutrients can muscular energy be produced?
12. Describe some of the chief processes that occur in the production of muscular movements.
13. Compare the requirements for a work animal with those for maintaining the same animal when idle, considering: (a) Total digestible nutrients or net energy; (b) protein; (c) minerals and vitamins.
14. Discuss the efficiency of the animal as a machine for the production of work.
15. What are the effects of fatigue, speed, lameness, and build of the animal on the economy with which work is produced?
16. Of what is wool composed?
17. Discuss the food requirements for wool production, and state what effects unfavorable feed or conditions may have upon wool.

CHAPTER XI

BALANCED RATIONS—FEEDING STANDARDS

I. Balanced Rations

316. Purpose of feeding standards.—To guide farmers in selecting properly balanced rations for their livestock, scientists have prepared *feeding standards.* These are tables stating the amounts of nutrients which, it is believed, should be provided in rations for farm animals of the various ages and classes in order to secure the best results.

Before reviewing the history of feeding standards and comparing the recommendations made by various scientists, let us compute a ration, balanced according to the recommendations of a feeding standard, to show how these aids in stock feeding are used. We will compute the ration according to the total digestible nutrient method, as this is the method most commonly used in the United States.

Previous to computing a ration for any class of stock, one should be sure that he has in mind the general requirements of satisfactory rations for that class of stock. These are discussed in the respective chapters of Part III.

317. A balanced ration for a dairy heifer.—Let us assume that a dairy farmer wishes to compute a balanced winter ration for a dairy heifer weighing 400 lbs., which is no longer being fed milk. He has available plenty of good alfalfa hay, ground corn grain (No. 2 grade), and ground oats. A study of the practical recommendations in Chapter XXVII for feeding dairy heifers shows that these feeds, in proper combination, are excellent for this purpose.

The next step is to find the amounts of nutrients recommended for heifers of this age in an up-to-date feeding standard. By turning to Appendix Table III, which presents the complete Morrison feeding standards, we find that the recommendations for a 400-lb. dairy heifer per head daily, according to these standards, are as follows: Dry matter, 9.1 to 11.4 lbs.; digestible protein, 0.76 to 0.87 lb.; and total digestible nutrients, 6.0 to 7.0 lbs.

The standards also show that the ration for such a heifer should contain 13 grams (0.029 lb.) of calcium, 9 grams (0.020 lb.) of phosphorus, and 24 milligrams of carotene. We will first compute a balanced ration that meets the recommendations for digestible protein and total digestible nutrients, and then see if it supplies sufficient calcium, phosphorus and carotene.

The Morrison feeding standards also state the amounts of net energy, expressed in therms, that are recommended for the various classes of animals. These net energy recommendations are used, instead of the amounts of total digestible nutrients, if one wishes to compute a ration according to the net energy system. (68) They are not used at all in computing a ration according to total digestible nutrients.

The amounts of dry matter recommended in the standard mean that a heifer of this size has a digestive tract that is sufficiently large for her to consume 9.1 to 11.4 lbs. of dry matter a day in her feed. This amount of feed should furnish 0.76 to 0.87 lb. digestible protein and 6.0 to 7.0 lbs. total digestible nutrients.

For two different reasons, a range is indicated in the amounts of digestible protein, of total digestible nutrients, and of dry matter recommended in the Morrison standards. First, economic conditions should determine whether it is better to use the lower or the higher figures for digestible protein or for total digestible nutrients. When protein-rich feeds are not unduly expensive, the author be-

lieves it is best to supply enough digestible protein to meet the higher recommendations. On the other hand, when protein supplements are unusually high in price, it may be more economical to furnish only enough digestible protein to meet the lower recommendations.

Similarly, the author believes that the results will generally be best when livestock are fed the higher amounts of total digestible nutrients stated in the standards. However, when grain and other concentrates are unusually expensive compared with roughages, it will be more economical to follow the lower recommendations and feed less concentrates.

50.7 per cent of total digestible nutrients. According to the standards, the heifer should receive 6.0 to 7.0 lbs. of total digestible nutrients a day. As we desire the heifer to make excellent growth, we will feed her a ration that will supply about 7.0 lbs. of total digestible nutrients.

Since each pound of hay furnishes 0.507 lb. of total digestible nutrients, the amount of hay needed to provide approximately this amount of total digestible nutrients can be found by dividing 7.0 lbs. by 0.507 lb. This gives a result of 13.8 lbs. This amount of hay will furnish the amounts of dry matter and digestible nutrients shown in the table:

First trial ration for 400-lb. dairy heifer

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Requirements	9.1–11.4	0.76–0.87	6.0–7.0
Alfalfa hay, 13.8 lbs.	12.5	1.50	7.00

The second reason for having a range in the amounts of nutrients recommended in the standards is that feeding standards can be only approximate guides. It has been pointed out in previous chapters that individual lots of the same kind of feed may differ considerably in chemical composition and in feeding value. Also, individual animals differ in ability to digest and utilize feeds.

In general, a ration made up of suitable feeds will be satisfactory, if the amounts of dry matter and of digestible nutrients fall within the limits set in the standard for that particular animal.

318. Computing the ration.—Before proceeding to compute a balanced ration, one should first write down in tabular form the requirements for the particular animal, as in the following table.

Let us next see how nearly a ration of only alfalfa hay would come to meeting the requirements for this heifer. Appendix Table I shows that alfalfa hay of average quality (alfalfa hay, all analyses) supplies 90.5 per cent of dry matter, 10.9 per cent of digestible protein, and

This ration supplies even more digestible protein than necessary and furnishes 7.00 lbs. of total digestible nutrients, but it is too high in dry matter. This means that the ration is too bulky and that it is too low in digestible nutrients per pound of dry matter. In other words, the heifer will not be able to eat enough hay to meet fully her need for total digestible nutrients. To make the ration satisfactory, it is therefore necessary to replace part of the hay by grain or other concentrates.

In the discussion of rations for dairy heifers in Chapter XXVII, it is stated that when heifers of this age are fed good roughage, an allowance of 2 to 4 lbs. of concentrates per head daily should be enough. **(1149)** It is also stated there that, when heifers are fed plenty of legume hay as the only roughage, grain alone is satisfactory for the concentrates.

Let us therefore see if the requirements will be met fully, if we use 3 lbs. of a mixture of one-half ground corn (Grade No. 2) and one-half ground oats, and reduce the amount of hay, so that the amount of total digestible nutrients will be about the same as before.

This will make possible the reducing of the hay allowance to 9.4 lbs. a day. The ration will then provide the following:

Balanced ration for 400-lb. dairy heifer

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Requirements	9.1–11.4	0.76–0.87	6.0–7.0
Ration			
Alfalfa hay, 9.4 lbs.	8.51	1.02	4.77
Corn, No. 2, 1.5 lbs.	1.28	0.10	1.20
Oats, 1.5 lbs.	1.35	0.14	1.05
Total	11.14	1.26	7.02

This ration supplies 7.0 lbs. total digestible nutrients, and the amount of dry matter comes within the range indicated in the standard. The amount of digestible protein is considerably higher than necessary, but this surplus of protein will not be at all detrimental. (108)

We should next see whether this ration provides sufficient calcium, phosphorus, and carotene. The percentages of calcium and phosphorus in these feeds are given in Appendix Table I and the amounts of carotene, expressed in terms of milligrams per pound, in Appendix Table V. From these data, we will find on computation that this ration supplies 0.140 lb. of calcium, while the requirement is only 0.029 lb. There is therefore an abundance of calcium. This is due to the high calcium content of alfalfa hay.

The ration has 0.032 lb. phosphorus, which is well above the requirement of 0.020 lb.

If the alfalfa hay is of reasonably good quality, it should supply 9 milligrams of carotene per pound. The 9.4 lbs. of hay would thus furnish 84.6 milligrams of carotene, which is more than three times the minimum stated in the standard. In addition, if the corn is yellow corn, it will supply some carotene. Oats have practically no carotene.

There is therefore no need of any additional supply of calcium, phosphorus, or carotene.

319. A balanced ration with roughage low in protein.—If good legume hay had not been used as the only roughage or at least as the chief roughage for this heifer, it would have been necessary to feed a protein supplement to balance the ration. Let us suppose, for example, that only timothy hay and corn silage are available for roughages. Timothy hay of the usual quality is not very good as the only roughage for heifers, but satisfactory results can be secured, when it is combined with corn silage, and when sufficient protein supplement is fed.

Let us then see how nearly the requirements for this heifer will be met by a ration of 6.0 lbs. of timothy hay (average of all analyses in Appendix Table I), 10.0 lbs. of corn silage (corn silage, dent, well-matured, recent analyses), and the same amounts of corn and oats as in the preceding ration. We will then have the following:

Ration too low in protein for 400-lb. heifer

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Requirements	9.1–11.4	0.76–0.87	6.0–7.0
Ration			
Timothy hay, 6.0 lbs.	5.34	0.18	2.95
Corn silage, 10.0 lbs.	2.76	0.12	1.83
Corn, No. 2, 1.5 lbs.	1.28	0.10	1.20
Oats, 1.5 lbs.	1.35	0.14	1.05
Total	10.73	0.54	7.03

This ration falls considerably below the requirements in digestible protein. To balance it, let us replace some of the corn-and-oats mixture with linseed meal (linseed meal, expeller or hydraulic process, average of all analyses, in Appendix Table I).

The next step is to find how much of the corn-oats mixture must be replaced by linseed meal. The ration has only 0.54 lb. digestible protein. To bring it up to the higher allowance recommended in the standard, the amount of digestible protein must be increased by 0.33 lb. (0.87 lb. – 0.54 lb. = 0.33 lb.)

The 3 lbs. of corn-and-oats mixture has a total of 0.24 lb. digestible protein (0.10 lb. + 0.14 lb. = 0.24 lb.). Therefore, each pound of this mixture supplies 0.08 lb. digestible protein.

Appendix Table I shows that average linseed meal has 30.6 per cent digestible protein. Each pound thus furnishes 0.306 lb. digestible protein.

By replacing 1.0 lb. of the corn-oats mixture with 1.0 lb. of linseed meal, the amount of digestible protein will be increased 0.226 lb. (0.306 lb. – 0.080 lb. = 0.226 lb.). To find the amount of linseed meal that we must substitute for the corn-oats mixture, we divide 0.33 lb. (the increase needed) by 0.226 lb. (the increase made by substituting 1.0 lb. of linseed meal for 1 lb. of the corn-oats mixture). This gives us 1.5 lbs. as the answer. Thus to balance the ration in protein, it will be necessary to replace 1.5 lbs. of the corn-oats mixture with 1.5 lbs. of linseed meal.

If some such method is not used to find how much protein supplement is needed, it is often necessary to try out several combinations of feeds, before one finds the proper mixture to balance the ration. Time can also often be saved by using this method of computation, when the ration is either too low or too high in total digestible nutrients, and one wishes to make a certain definite change in the amount of total digestible nutrients by changing the proportions of roughage and concentrates.

The following table shows that this ration meets the requirements:

Second balanced ration for 400-lb. heifer

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Requirements	9.1–11.4	0.76–0.87	6.0–7.0
Ration			
Timothy hay, 6.0 lbs.	5.34	0.18	2.95
Corn silage, 10.0 lbs.	2.76	0.12	1.83
Corn, No. 2, 0.75 lb.	0.64	0.05	0.60
Oats, 0.75 lb.	0.68	0.07	0.53
Linseed meal, 1.5 lbs.	1.37	0.46	1.13
Total	10.79	0.88	7.04

This ration should be satisfactory, but it is not so good as a ration containing some legume forage.

It will be found on computation that this ration supplies an abundance of phosphorus, because of the high phosphorus content of linseed meal. It is stated in Chapter XXVII that there will generally be no lack of calcium for heifers fed plenty of roughage, even when it is non-legume, unless the soil is unusually low in calcium. (**1116**) By computation, it will be found that, according to average analyses, this ration supplies 0.037 lb. calcium, which is slightly above the requirement in the standard. However, when heifers are fed no legume forage whatsoever, it may be wise to supply a calcium supplement, to guard against a possible deficiency, if the hay and silage are lower than average in calcium.

Because of the good carotene content of corn silage, the ration will provide ample carotene.

320. "Square" method of balancing ration.—Another method of determining how much protein supplement is needed to balance a ration is the "square" method, which is used at milk plants to

find what proportions of milk and heavy cream, the fat percentages of which are known, are needed to make cream or milk containing a certain desired percentage of fat.

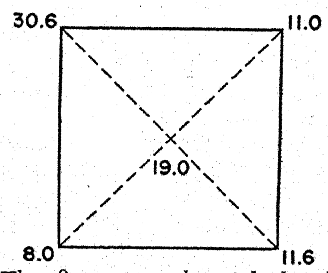
Let us employ this method to find what proportions of linseed meal and of the corn-oats mixture are needed to balance the same allowances of roughages used in the previous ration. The preceding table shows that the combination of 6.0 lbs. timothy hay and 10.0 lbs. corn silage furnishes a total of 0.30 lb. digestible protein.

To provide 0.87 lb. digestible protein in the entire ration, the concentrates must therefore provide 0.57 lb. digestible protein. If 3 lbs. of concentrate mixture are fed a day, each pound of the mixture must have 0.19 lb. digestible protein, or the percentage of digestible protein must be 19.0 per cent.

The question is, what proportions of linseed meal, having 30.6 per cent digestible protein, and of the corn-oats mixture, which we have previously found to have 8.0 per cent digestible protein, will give a mixture with 19.0 per cent digestible protein?

To use the "square" method, set down the percentages of digestible protein in the two components of the mixture at the left hand corners of a square. Connect the diagonal corners of the square with lines, and set down the desired percentage of protein in the center.

Then follow along the diagonal lines and set down in the right hand corners the differences between the figures at the left-hand corners and the figure in the center. The square will then appear as follows:



The figures at the right-hand corners show the proportions of linseed meal and of the corn-oats mixture it will take to give a digestible-protein content of 19.0 per cent. The number showing the parts of linseed meal in the mixture is directly opposite the percentage of protein in linseed meal, and the number showing the parts of the corn-oats mixture is opposite the percentage of protein in this mixture.

It is found by this simple method that a mixture composed of 11.0 parts or pounds of linseed meal and 11.6 parts or pounds of the corn-oats mixture will have the desired digestible protein content of 19.0 per cent. There will be 11.0 parts plus 11.6 parts, or 22.6 parts in the total combination.

The number of pounds of linseed meal in 100 lbs. of the mixture is found by dividing 11.0 by 22.6 and multiplying the quotient by 100. This gives us 48.7 lbs. of linseed meal in 100 lbs. of mixture. The rest, or 51.3 lbs., is the combination of one-half corn and one-half oats.

To simplify making up the mixture, it will be accurate enough if it is made up of 50 lbs. linseed meal, 25 lbs. ground corn, and 25 lbs. ground oats. It will be found that such a mixture, made from feeds of average composition, will supply 19.3 per cent digestible protein. The protein requirements will therefore be met well if 3 lbs. per head daily of this mixture are fed.

321. Finding the formula for a concentrate mixture.—In the practical feeding of livestock, it is not necessary to compute balanced rations for the individual animals in the herd or flock. Instead, a ration is found that will provide the proper amounts of nutrients for the average animal. Then, the amount of concentrates, or of both concentrates and roughage, may be varied for the various animals.

For example, in feeding a herd of dairy cows, the same concentrate mixture, or so-called "grain mixture," is generally used for all the cows, except perhaps for those that are exceptionally high producers. However, the *amount* of the concentrate mixture fed each cow should depend on her actual milk pro-

duction, as is emphasized in Chapter XXV.

The Grain Feeding Tables, given in Appendix Tables VIIIa and VIIIb, state definitely the amounts of grain mixture, or concentrate mixture, needed daily by cows producing different amounts of milk of the various fat percentages, and when supplied with different qualities and amounts of roughages. One of these tables is for barn feeding and the other for cows on different qualities of pasture. The use of these tables and the Example Rations given in Appendix Table VII will save much time in computing balanced rations for dairy cows.

322. Formula for a concentrate mixture.—To illustrate the way the formula for a concentrate mixture is found, let us compute a concentrate mixture, made up of ground corn, ground oats, wheat bran, and soybean oil meal, for feeding the same age of dairy heifers as in the previous example. We will use the same roughages as in the preceding example —6 lbs. of average timothy hay and 10 lbs. of well-matured corn silage.

We have seen in the preceding examples that 3 lbs. of a concentrate mixture are sufficient for such heifers. Also, in the ration with timothy hay and corn silage for roughage, it has been shown that to meet the higher protein recommendations in the standard, the concentrate mixture should have about 19.0 per cent digestible protein. This high protein content is needed, because no legume forage is available.

Let us now find the proportions of corn, oats, wheat bran (all analyses), and soybean oil meal (expeller or hydraulic process, 43 per cent protein guarantee) that will furnish this percentage of digestible protein. We will first try a mixture of 25 lbs. of each of these feeds. From Appendix Table I, we find that this mixture will supply the following amounts of digestible protein:

	Digestible protein Lbs.
Corn, No. 2, 25 lbs.	1.68
Oats, 25 lbs.	2.35
Wheat bran, 25 lbs.	3.33
Soybean oil meal, 25 lbs.	9.23
	16.59

Since 100 lbs. of this mixture contain 16.59 lbs. of digestible protein, the percentage of digestible protein is 16.59 per cent. This is somewhat less than is needed. We must therefore increase the proportion of a protein-rich feed in the mixture and decrease the amount of another feed correspondingly.

We desire to feed as large a proportion of home-grown corn and oats as possible. Since soybean oil meal is much richer than wheat bran in protein, we will increase the soybean oil meal and reduce the wheat bran. By trying out various combinations, we find that a mixture of 25 lbs. ground corn, 25 lbs. ground oats, 14 lbs. bran, and 36 lbs. soybean oil meal will have the desired percentage of digestible protein.

Let us now find the percentages of dry matter and of digestible nutrients in the concentrate mixture. This is done as follows:

Finding the composition of a concentrate mixture

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Corn, No. 2, 25 lbs.	21.25	1.68	20.03
Oats, 25 lbs.	22.55	2.35	17.53
Wheat bran, 14 lbs.	12.61	1.86	9.37
Soybean oil meal, 36 lbs.	32.90	13.28	28.30
In 100 lbs. of mixture	89.31	19.17	75.23

Having found the composition of this concentrate mixture, we can use these figures in working out a ration, just like the figures in Appendix Table I for the various single feeds. Let us now check this ration to see whether it fully meets the needs of 400-lb. dairy heifers. We will then have the following:

Balanced ration, using preceding concentrate mixture

	Dry matter Lbs.	Digestible protein Lbs.	Total digestible nutrients Lbs.
Requirements	9.1–11.4	0.76–0.87	6.0–7.0
Ration			
Timothy hay, 6.0 lbs.	5.34	0.18	2.95
Corn silage, 10.0 lbs.	2.76	0.12	1.83
Concentrate mixture, 3.0 lbs.	2.80	0.58	2.26
Total	10.90	0.88	7.04

This ration fully meets the requirements stated in the standard.

323. Finding the percentage of protein needed in a mixed feed.—If one desires to use a commercial mixed feed instead of a home-prepared concentrate mixture, the question arises as to the percentage of protein needed in the mixed feed to make a balanced ration with the roughage available.

In the case of most mixed feeds on the market, while the percentage of total protein is guaranteed, the percentage of digestible protein in the feed is not stated. Therefore, it is necessary to find the approximate percentage of total protein required in the mixed feed to make a balanced ration with the roughage that is to be fed. This can be done as follows:

Let us assume that by such computations as in the previous examples, we have found that with plenty of good-quality mixed clover-and-timothy hay and corn silage for roughage, a herd of dairy cows needs a concentrate mixture having about 14.5 per cent digestible protein to make a balanced ration.

In most good mixed dairy feeds approximately 80 per cent of the total protein is digestible. On this basis, the necessary percentage of total protein in a mixed feed may be found by dividing 14.5 per cent by .80 and multiplying by 100. This gives us a result of 18.1 per cent, which means that a good-quality mixed feed which supplies 14.5 per cent *digestible protein* will contain about 18 per cent *total protein.* A mixed dairy feed that is guaranteed to contain 18 per cent protein should therefore be satisfactory for feeding with such roughage.

324. Guides in selecting efficient balanced rations.—Before attempting to compute economical balanced rations for any class of stock, it is important to read the explanations and general hints in the following paragraphs and in the next chapter. Also, one should study the information given in Part III on how to make up efficient rations for that particular class of stock. It is impossible to compute satisfactory and economical rations if reliance is placed only on the amounts of nutrients recommended in feeding standards.

As a guide to students and stockmen alike, the author has computed example balanced rations for the different classes of stock, which are adapted to various conditions. These rations are given in Appendix Table VII. Often, one will be able to find among these suggestions a ration that will exactly meet his particular conditions. Even when the feeds that are available differ somewhat from those included in the example rations, these rations will serve as convenient guides and will save much time in computation.

Unless a person is experienced in stock feeding, he may not know what proportions or amounts of roughages and concentrates there should be in rations for any class of stock. As has already been shown in this chapter, the amounts of dry matter and of total digestible nutrients recommended in the feeding standard for a particular kind of stock are a guide to the proper proportion of roughages and concentrates in the ration.

When the requirement of digestible nutrients or of net energy is high compared with the total amount of dry mat-

ter advised, the proportion of concentrates in the ration must be large to meet the standard. On the other hand, for merely maintaining horses, cattle, or sheep the allowance of digestible nutrients or net energy is much smaller, in comparison with the amount of total dry matter. This is because these animals can be maintained largely or entirely on roughage.

In Appendix Table III there will be found, immediately previous to the Morrison feeding standards, convenient guides which show the approximate proportions of roughages and concentrates required by the various classes of stock. By referring to these guides, much time can often be saved in computing balanced rations.

AN UNSATISFACTORY AND EXPENSIVE "BALANCED" RATION

This ration of 20 lbs. late-cut timothy hay, 3 lbs. ground corn, 2 lbs. ground oats, 3 lbs. wheat bran, and 3.5 lbs. linseed meal, meets the standard for a 1,200-lb. cow yielding 30 lbs. of 3.5 per cent milk. However, late-cut timothy hay is a poor roughage for dairy cows, because it is unpalatable, poor in protein, and low in total digestible nutrients. A cow will not eat as much of such hay as of good-quality hay. Therefore, 11.5 lbs. of concentrates are needed. Even then, the milk production will be lower than with good roughage. (From Wisconsin Station.)

II. GENERAL REQUIREMENTS FOR SATISFACTORY RATIONS

325. Feeding standards only approximate guides.—It has been shown in Chapter IV that there may be considerable difference in the composition and feeding value of two different lots of the same kind of feed. Also, individual animals may differ somewhat in their ability to digest and utilize feed. These facts must be taken into consideration in the preparation of feeding standards. The recommendations must therefore provide a sufficient margin of safety to cover the usual variations in the composition of feeds and the differences in the individual animals to be fed.

Animals on pasture need a somewhat greater amount of total digestible nutrients per head daily than those confined to a stable most of the time. This is because of the additional energy used up in the muscular work of grazing.

The author believes that, except when protein-rich feeds are unusually expensive, it is best to supply about as much protein as called for by the higher set of recommendations in the standards. On the other hand, if protein supplements are high in price, in comparison with grains or other low-protein feeds, it will probably be more economical to provide no more than the lower amounts of digestible protein in the standards.

When protein supplements are extremely high in price, it may be most economical to feed slightly less protein than called for by the lower set of recommendations, even though the rate of production may be decreased somewhat. At the other extreme, when protein-rich feeds are cheaper than those low in pro-

tein, it is usually economical to furnish even a greater amount of protein than stated in the higher set of protein allowances in the standards. As has been shown in Chapter V, any ordinary excess of protein is not injurious to farm animals. (**108**)

326. Quality of protein.—The amounts of digestible protein recommended in the feeding standards for the various classes of stock are based on the assumption that protein of average quality will be furnished. It has been shown in Chapter V that the quality of protein is of much greater importance in the feeding of swine and poultry than for cattle, sheep, or horses. (**112, 127**) The only exception is in the case of very young calves being raised on a minimum amount of milk. In feeding swine and poultry it is necessary to give fully as much attention to the *quality* of protein in the ration as to the *amount*.

Information on the quality of the protein in various feeds is presented in Chapter V and in the discussions of the individual feeds in Part II. Full consideration has been given to the importance of proper quality of protein in the rations suggested for the various classes of stock in Appendix Table VII and in the chapters of Part III.

327. Suitability of feeds; palatability.—The feeds selected for any animal should be such that they will not injure its health or impair the product yielded. Feeds which are suited to one class of animals may not be suited to others. Again, a given feed may give satisfactory results when combined with certain feeds, yet in other combinations it may be unsatisfactory. Detailed information is given in Part II concerning the value and use of the many feeding stuffs for the various classes of stock. One can readily learn whether any particular feed is suitable for a given class of stock

A RATION WHICH IS GOOD, BUT LACKS SUCCULENCE

This ration of 25 lbs. good-quality red clover hay, 3 lbs. ground corn, 2.5 lbs. ground oats, and 2 lbs. wheat bran furnishes no more total digestible nutrients than the previous one, but it will produce more milk, because clover is far superior to late-cut timothy hay as a roughage. Only 7.5 lbs. concentrates are needed in this ration. (From Wisconsin Station.)

by consulting the index to find the pages where information about it is given.

The palatability of the ration is important in feeding livestock for production. The wise farmer will utilize feeds of low palatability chiefly for animals which are being merely maintained, and will feed milk cows, growing and fattening animals, and horses or mules at hard work rations made up mostly of well-liked feeds.

Some concentrates, such as malt sprouts and distillers dried grains, which may not be relished when fed alone, are entirely satisfactory if mixed with better-liked feeds. Similarly, if such low-grade roughage as straw is combined with good hay that provides plenty of vitamins, a limited amount can even be fed to dairy cows or to fattening cattle and sheep.

In this country it is not usually ad-

visable to use very low-grade roughage for stock being fed for production, except in emergency. However, in Europe such roughage as straw is often chopped and mixed with the concentrates, the mass being moistened and allowed to stand for a few hours, until the roughage becomes softer and more palatable.

Livestock will usually yield the maximum amount of product only on rations made up entirely or chiefly of palatable feeds. However, it should be borne in mind that an important function of our farm animals is to convert into useful products materials that would otherwise be wasted.

328. Cost of the ration.—The most important factor of all for the farmer who must depend on the profits from his stock for his income, is the cost of the ration. In securing a ration which provides the nutrients called for by the standards and meets the other conditions previously discussed lies a great opportunity for exercising foresight and business judgment.

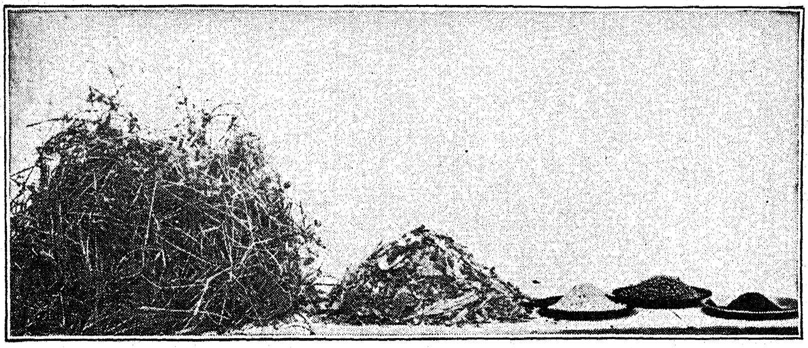
The wise stockman will consider the requirements of his animals in planning his crop rotations. Through the use of farm-grown grain, legume hay, and such cheap succulence as silage from corn or the sorghums, or from hay crops, it is possible in most sections of the country to go far toward providing a well-balanced, economical ration. Methods of determining which feeds are most economical are described in the following chapter.

III. Feeding Standards

329. Early feeding standards.—The first feeding standards based on the digestible nutrients in feeds were presented by Wolff, a German scientist, in 1864. The Wolff standards were modified somewhat in 1896 by Lehmann, another German scientist, as there was then further information concerning the nutritive requirements of livestock. These standards, known as the Wolff-Lehmann feeding standards, were widely used for many years in Europe and also in America in computing balanced rations for livestock. They have been superseded by modern standards.

Feeding standards based on net energy were presented in 1907 by Kellner in Germany[1] and in 1917 by Armsby in this country.[2] It has been explained in Chapter III that the Kellner standards were expressed in starch values, while the Armsby standards were stated in therms of net energy.

In both the Kellner and the Armsby



An Excellent and Economical Ration for Milk Production

This ration of 12 lbs. good-quality red clover hay, 36 lbs. well-eared corn silage, 3 lbs. ground corn, 1.5 lbs. wheat bran, and 2.25 lbs. cottonseed meal is far superior to the first ration and even better than the second. The feeds are all palatable and suitable for dairy cows, and the silage provides succulence. Only 6.75 lbs. of concentrates are needed with the good clover hay and the well-eared corn silage, to furnish as much total digestible nutrients as in the first ration, which has 11.5 lbs. concentrates. (From Wisconsin Station.)

standards the protein recommendations were stated in terms of digestible true protein, instead of digestible crude protein. These standards did not therefore credit the simpler nitrogenous substances in feeds with any value as a substitute for proteins. This point of view has now generally been discarded, as has been mentioned previously. (18) It is therefore much preferable to express the protein requirements of animals in terms of digestible protein (digestible crude protein), as is done in most of the recent feeding standards used in this country.

330. Later feeding standards.—Several different feeding standards for dairy cows have been presented by various scientists, including Haecker, Eckles, Savage, Forbes, Ellett and associates, Möllgaard, Brody, Gaines, and Baker. Lack of space does not permit a discussion of the recommendations in these various standards. However, it is of especial interest to note that Haecker was apparently the first to recognize in his standards that the amount of nutrients a cow requires depends not only on the amount of milk she produces, but also on its richness in fat. The Scandinavian feed unit system has been discussed in Chapter III. (84)

Standards for certain other classes of stock have also been prepared by various scientists. These are mentioned in the chapters of Part III in which the nutrient requirements of the various classes of stock are considered.

Fraps of the Texas Station presented some years ago feeding standards expressed in terms of dry matter, digestible crude protein, and productive value, stated in therms of net energy.[3] These productive values are thus given in the same terms as Armsby's net-energy values.

Recently the National Research Council has published a series of reports, prepared by special committees, which state the amounts of nutrients advised for the various classes of farm animals.[4] The recommendations for the various classes of stock are discussed in the respective chapters of Part III of this volume.

331. The Morrison feeding standards.—Until 1915 the old Wolff-Lehmann feeding standards were used more commonly in the United States than any others, except for dairy cows. In computing rations for milk production, these German standards had been largely replaced by the more accurate American standards, especially by the Haecker standards, the Savage standards, and the Eckles standards. For other classes of stock the Wolff-Lehmann standards were commonly used, although they advised larger amounts of protein than necessary and were not well adapted to American conditions.

At that time the need for modern standards for the various classes of stock was deeply impressed upon the author of this volume. For example, he found that certain companies which annually fattened thousands of cattle and sheep were carefully computing rations with these out-of-date standards. In order to balance the rations according to these standards, they were spending large sums of money for entirely unnecessary amounts of protein supplements, thus considerably reducing their profits.

Neither the Kellner nor the Armsby feeding standards had been widely adopted in this country, for instructors and farmers seemed to prefer standards based on digestible nutrients instead of energy values. The author therefore endeavored to combine in one set of standards what seemed in his judgment to be the best guides available in the computation of rations for the various classes of stock. These standards were first presented in the fifteenth edition of *Feeds and Feeding*, published in 1915, and were then called the "Modified Wolff-Lehmann Standards." They soon came to be known as the Morrison feeding standards.

To lessen the work of computing rations, the standards were expressed in terms of dry matter, digestible protein, and total digestible nutrients, instead of giving separate recommendations for digestible carbohydrates and for digestible fat, as in the Wolff-Lehmann standards. Also, for the reasons stated previously, in

each recommendation in the standards, there was a range in the amounts of dry matter, digestible protein, and total digestible nutrients advised, instead of only one figure being given.

In order to incorporate the results of later investigations, extensive changes were made in the standards in 1936, and the revised recommendations were published in the 20th edition of *Feeds and Feeding*. For those who desired to use net-energy values instead of total digestible nutrients in computing rations, a column was also added which stated the net-energy allowances advised, expressed in therms.

Based upon the further information then available concerning the nutrient requirements of farm animals, extensive changes were made in the standards presented in the 21st edition of *Feeds and Feeding*, published in 1948, and additional changes have been made in the standards given in the present edition. Recommended allowances are now given for calcium, phosphorus, and carotene.

In revising the standards the author has given careful consideration to all recent publications concerning the nutrient requirements of the various classes of livestock. Of especial help in making the revisions have been the reports published by the National Research Council, which have been mentioned previously. In these reports no range is given in the amounts of nutrients recommended for a particular class of animals. In other words, only one figure is given for digestible protein or for total digestible nutrients. For the reasons stated previously, the author prefers to give a range in the amounts of nutrients advised for each class of animal.

Also, in certain of these reports, the total amounts of feed advised are stated in terms of "air-dry feed" instead of in terms of dry matter. Since the moisture content of dry roughage varies considerably in various regions, depending on the humidity of the air, the author prefers to express recommendations in terms of dry matter.

332. Computing rations according to the Morrison standards.—The method of computing rations based on the digestible nutrient recommendations in the Morrison standards has been fully described in the first part of this chapter. In computing rations according to total digestible nutrients, one should entirely disregard the net energy figures which are given in the last column of the various pages of Appendix Table III. He should use the recommendations given for dry matter, digestible protein, and total digestible nutrients, and should consult Appendix Table I to find the corresponding composition of the various feeding stuffs.

However, if one desires to compute rations according to the net energy system, he should disregard the recommended allowances of total digestible nutrients, and should use instead the net energy values shown in the last column of figures. The estimated net energy values of the most important feeds, for use in this method of computing rations, are stated in Appendix Table II. This table also gives the percentages of dry matter and of digestible protein in these feeds.

Except for the difference in the figures used, the method of computing a ration according to the net energy system is the same as when total digestible nutrients are used. It is therefore not necessary to present an example of the use of this method.

QUESTIONS

1. What are feeding standards?
2. Compute a ration according to the Morrison feeding standards for wintering a yearling dairy heifer weighing 700 lbs. In this and the following problem use feeds available in your locality and find the cost of the ration.
3. Compute a ration according to the Morrison feeding standards for 1,200-lb. dairy cows producing an average of 40 lbs. of milk containing 3.5 per cent fat daily. Determine first the necessary percentage of digestible protein in the concentrate mixture to feed with the roughages you select, using the method shown in Article 321. Then work out a formula for a satisfactory concentrate mixture, containing this percentage of digestible protein. Finally,

compute the dry matter, the digestible protein and the total digestible nutrients in the entire ration, to see whether or not it meets the requirements.

4. If you wished to use a good commercial dairy feed for these cows, approximately what percentage of total protein should it contain?
5. What guide do the Morrison feeding standards furnish as to the proper proportion of roughages and concentrates for a particular class of stock?
6. What factors not included in the recommendations of feeding standards must be considered in computing efficient rations for stock?
7. Why have the Wolff-Lehmann feeding standards been superseded by other feeding standards?
8. In what terms are the nutrient requirements expressed in the Armsby feeding standards; in the Kellner feeding standards?
9. What important advance did Haecker make in feeding standards for dairy cows?
10. In what terms are the nutrient requirements of livestock expressed in the Morrison feeding standards?
11. Why is a range indicated in the recommendations given in these standards for each class of stock, instead of only one figure being given for dry matter, digestible protein, and total digestible nutrients, respectively?

CHAPTER XII

ECONOMY IN FEEDING LIVESTOCK

I. Selecting Economical Rations

333. Providing efficient rations at least expense.—One farmer often secures much greater net returns from his livestock than does a neighbor, because he gives more thought to the selection of rations that are not only well balanced but also as economical as possible.

First of all, he grows those crops which have the highest feeding value. He also plans his crop rotations so that he has an abundance of high-quality hay and other roughage for winter feeding and excellent pasture throughout the growing season. If possible, he raises plenty of legume forage crops, so that he will not need to buy large amounts of protein supplements. Finally, in buying protein supplements or other feeds, he uses good judgment in selecting those which are most economical under his local conditions.

334. Guides in selecting economical rations.—It often takes careful study to find which of several available feeds are actually most economical. This is because the market price of the various feeds may not be a guide to their real feeding value. For example, one year there may be a short oat crop in this country, but a good crop of corn. This will make oats unusually expensive in comparison with corn. The next year the conditions may be reversed, and oats will then be an economical feed. Similarly, the relative prices of the various protein supplements vary considerably from year to year, and sometimes there are wide changes in the relative prices of feeds even during a single year.

To secure the most profit from livestock, it is necessary to give careful attention to the changes in feed prices. One should not get into the habit of feeding the same combination of feeds year after year, regardless of whether these feeds are cheap or costly. Experiments have shown that there is no one best ration for any class of stock. Therefore when feed prices change decidedly, one should make whatever changes are necessary in his rations to take advantage of the new conditions.

To aid stockmen in selecting rations that will be economical under different conditions, there are given in Appendix Table VII a considerable number of balanced rations for the various classes of animals. Any of these should give excellent results when composed of good-quality feeds and fed to thrifty animals. Many additional suggestions will be found in the chapters of Part III.

335. Determining which feeds are actually cheapest.—It has been emphasized previously in Chapter III that the best guide to the relative values of different feeds for any class of stock is provided by the results of actual feeding experiments with the same class of animals. (58–59) The statements made in later chapters concerning the values of the various feeds are therefore based chiefly upon extensive studies made by the author of the results of such experiments.

As yet, the relative values of only certain of the most important feeds have been determined by means of feeding experiments with the various classes of stock. For other feeds we must base our comparisons on their content of digestible nutrients or net energy and on the general information about their usefulness for the particular kind of animal.

One method of comparing the economy of feeds is to compute the cost per pound of total digestible nutrients in each feed. This shows which feeds supply total digestible nutrients at least expense. It is a correct method of compar-

ing the values of feeds when protein-rich feeds cost no more than those rich in other digestible nutrients.

However, in most parts of the United States feeds that are rich in protein generally cost more than those which are low in protein but rich in carbohydrates. Digestible protein then has a greater value per pound than digestible carbohydrates. Under such conditions some method should be used which takes into account not only the amounts of total digestible nutrients but also the amounts of digestible protein in the various feeds.

Sometimes the method is used of computing for each feed not only the cost per pound of total digestible nutrients, but also the cost per pound of digestible protein. However, even with this information, it is often difficult to decide which feeds are most economical. For example, one protein supplement may furnish digestible protein at the least cost, while another is a cheaper source of total digestible nutrients. Considerable experience is necessary to balance one factor against the other in estimating the actual relative economy of the two feeds.

Another method is to place a definite price on each pound of total digestible nutrients and an additional value on each pound of digestible protein there is in the feed.[1] These prices are determined from the market price of a common or base carbohydrate-rich feed, such as corn grain, and the price of a common protein supplement. Tables can be worked out on this basis which show the relative money values of various feeds. However, any such table can be used only so long as the base feeds do not change in price. The method therefore has only limited usefulness.

336. The Petersen method of valuing feeds.—Petersen of the Minnesota Station devised an ingenious method which can be used to determine the relative values of various feeds even when the prices of the base feeds change decidedly.[2] He took corn and cottonseed meal as the base feeds, since corn is the most common carbohydrate-rich concentrate in this country and cottonseed meal was then the most important high-protein supplement. However, other base feeds may be used in the same manner. Since soybean oil meal has now become the most important protein supplement in the United States, let us take it as the base protein-rich feed in our discussion of this method.

It is evident that whenever protein-rich feeds cost more than carbohydrate-rich feeds, as is usually the case, then the actual relative value of any other feed will depend partly on the price of the standard or base carbohydrate-rich feed and partly on the price of the base protein-rich feed. Two factors are therefore computed for each feed to be valued. One of these, called the "constant for corn," shows the extent to which the price of corn per ton affects the value of the given feed. The other factor, called the "constant for soybean oil meal," shows the extent to which the price of soybean oil meal per ton affects the value of the particular feed in question.

Constants of this kind for the most important feeds are given in Appendix Table II. These have been computed from the estimated net-energy value and the digestible protein content of each feed, which values are also given in this same table. The net-energy values of the various feeds have been used in computing these factors, instead of the content of total digestible nutrients, because of the reasons stated in Chapter III. (77) In the opinion of the author, net-energy values provide a more accurate basis than do total digestible nutrients for comparing the values of various feeds for productive purposes. This is especially true when one wishes to compare a concentrate that has considerable fiber with one which is low in fiber and high in digestibility and productive value. The difference is even greater in comparing a high-grade concentrate with hay or other dry roughage.

In computing these factors, solvent-process soybean oil meal has been taken as the base protein-rich feed, because of its importance. Dent corn of Federal Grade No. 2 has been taken as the base carbohydrate-rich feed.

To illustrate the method of using these constants, let us compute the value of corn gluten feed for dairy cows as a source of digestible protein and of net energy, in comparison with ground corn (Grade No. 2) at $60.00 per ton and soybean oil meal at $80.00 per ton.

In the case of feeds which apparently have a higher relative value for dairy cows than for meat production, separate net energy values and feed evaluation constants for dairy cows are given in Appendix Table II. This is the case with corn gluten feed.

By referring to the table, we find that the "Constant for corn" of corn gluten feed for dairy cows is 0.456, and the "Constant for soybean oil meal" is 0.434. To find the value of corn gluten feed, we multiply the price of corn by 0.456, the "Constant for corn;" and next we multiply the price of soybean oil meal by 0.434, the "Constant for soybean oil meal;" and finally we add the products. This gives us $62.08 as the value of corn gluten feed for dairy cows, in comparison with corn and soybean oil meal at the particular prices stated in this example.

337. Graphs for finding the relative values of feeds.—In order to make these computations unnecessary, Petersen has also devised convenient graphs, from which the relative values of feeds can be easily read, with corn and cottonseed meal at any particular prices. Such graphs have distinct advantages over the use of the "constants." First, no computation whatsoever is required. Second, if some other protein-rich feed is decidedly cheaper than cottonseed meal or whatever protein supplement is used as the base feed, it may be taken as the standard protein-rich feed in using the graphs. Likewise, barley or one of the other small grains may be used as the standard low-protein feed, if one of these grains is cheaper or more available locally than corn.

To be used accurately, graphs of this kind must be of larger size than can be included in such a volume as this. Also, only a few feeds can be given in each graph, as otherwise the lines for various feeds would fall too close together to be legible.

It has been pointed out previously that when protein-rich feeds cost no more or even less than those low in protein, the amount of total digestible nutrients (or net energy) should be used as the basis for determining the relative values of various feeds. To make such comparisons possible without any need for computations, graphs have also been devised from which the relative values of the important feeds can be determined at a glance, taking as a standard of comparison one of these feeds at any particular price.

338. A comparison of corn-belt feeds for dairy cows.—To illustrate the manner in which the relative economy of different feeds may be determined by using the constants in Appendix Table II, let us assume that a dairyman in the corn belt has plenty of the following home-grown grains: Shelled corn (Grade No. 2), worth $1.45 a bushel, or $51.79 a ton, on the farm; oats, worth $.86 a bushel, or $53.75 a ton; and barley of good brewing grade, worth $1.33 per bushel, or $55.42 a ton. He wishes to feed his cows the grain which is cheapest, considering its feeding value, and to sell that which is highest priced.

It will cost about $3.50 a ton to grind these grains, as should be done for dairy cows. This will make the farm price of ground corn $55.29 a ton; of ground oats, $57.23 a ton; and of ground barley, $58.92 a ton.

To balance the ration the following protein supplements are available on the local market: Corn gluten feed at $60.00 per ton; cottonseed meal (41 per cent protein grade), $70.00 per ton; distillers dried corn grains (without solubles), $67.00 per ton; linseed meal, $75.00 per ton; soybean oil meal (solvent process), $75.00 per ton; and wheat bran, $50.00 per ton. Cane molasses is also available at $48.00 per ton in barrels. If it could be secured locally from a tank car, the price would be much lower.

Limited amounts of these feeds can be hauled home on return trips from town without much of an additional

cartage expense. It is not assumed that these prices represent average conditions in any section of this country, but they are merely taken to illustrate the manner in which the relative economy of various feeds may be compared.

We will assume that this farmer has for his cows plenty of good mixed clover-and-timothy hay containing one-third to one-half clover, and in addition has enough corn silage to feed throughout the winter. With such roughage, a concentrate or "grain" mixture containing about 18 per cent total protein or 14.5 per cent digestible protein will provide enough protein for good production. (See Articles **323** and **1017**, and also the example rations in Appendix Table VII.) Let us therefore compute an economical concentrate mixture which will supply about 14.5 per cent of digestible protein.

First, we will compute from the constants in Appendix Table II the values per ton of the various feeds, taking corn and soybean oil meal as the base feeds, or the standards of comparison. We will set these values down in tabular form, along with the market prices of the various feeds. We will then set down for each feed the amount by which its computed value per ton is greater or less than the market price. This will give us the following table.

The table shows that with feeds at these particular prices, wheat bran is the only other concentrate that supplies digestible protein and net energy as cheaply as do corn and soybean oil meal. Ground barley is worth for feeding $1.74 less per ton than the farm price. It will therefore be most economical to feed ground corn as the chief grain and to sell the barley.

If fed as the chief grain to dairy cows, ground oats is worth considerably less than the current price. However, when not over 25 per cent of ground oats is included in the mixture, oats has a higher value and is nearly as economical as ground corn. This higher value for oats when forming not more than 25 per cent of the concentrate mixture is based upon numerous experiments which are summarized in Chapter XX.

Cane molasses is slightly less economical at the price of $48.00 per ton than ground corn at the farm price of $55.29 per ton. It should therefore be used only if needed to increase the palatability of a ration that might otherwise not be well liked.

339. Choosing an economical concentrate mixture.—This dairyman wishes to use a concentrate mixture made up as largely as possible of his home-grown grains. From the standpoint of economy

Comparison of economy of various concentrates at prices stated

	Price of feed per ton Dollars	Value of feed per ton Dollars	Difference per ton between price and value Dollars
Farm grains			
Barley, ground (*for dairy cows*)	58.92	57.18	−1.74
Corn, dent, ground	55.29	55.29	....
Oats, ground, as chief grain	57.23	51.69	−5.54
Oats, ground, not over 25% of concentrates	57.23	56.74	−0.49
Purchased concentrates			
Corn gluten feed (*for dairy cows*)	60.00	57.76	−2.24
Cottonseed meal, 41% protein	70.00	65.06	−4.94
Distillers dried corn grains, without solubles	67.00	64.91	−2.09
Linseed meal, expeller or hydraulic process, 32% protein grade	75.00	66.40	−8.60
Molasses, cane, not over 10% of concentrates	48.00	45.82	−2.18
Soybean oil meal, solvent process	75.00	75.00	....
Wheat bran	50.00	50.57	+0.57

he will therefore use ground corn as the chief part of the mixture.

When forming not over 25 per cent of the concentrates, ground oats is nearly as economical as ground corn, and oats will add bulk to the mixture. At the prices stated, wheat bran is a cheap feed, and a little bran will add bulk and variety. (1071)

At these prices the most economical concentrate mixture will be a combination of ground corn, ground oats, soybean oil meal, and wheat bran. A little figuring will show us that a mixture of 500 lbs. ground corn, 210 lbs. ground oats, 190 lbs. soybean oil meal, and 100 lbs. wheat bran will supply the desired percentage of digestible protein. This is shown in the following table:

An economical concentrate mixture with feeds at the prices stated

	Digestible protein Lbs.	Cost Dollars
Corn, ground, 500 lbs.	33.5	13.82
Oats, ground, 210 lbs.	19.7	6.01
Soybean oil meal, 190 lbs.	79.8	7.13
Wheat bran, 100 lbs.	13.3	2.50
Total in 1,000 lbs.	146.3	29.46
Per 100 lbs.	14.6	2.95

This mixture will be very economical under these particular conditions, and it should produce excellent results, for it is made up of feeds of high nutritive value and feeds that are well liked by dairy cows. Some dairymen might prefer a concentrate mixture with greater variety, containing a greater number of different feeds. However, at these particular prices other feeds could not be included in the mixture without somewhat reducing the economy.

340. Changing the mixture to meet changed feed prices.—To show how a ration should be modified to meet changed feed prices, let us assume that the next year the prices for some of the feeds have changed as shown in the following table:

Effect of changed prices on economy of various feeds

	Price of feed per ton Dollars	Value of feed per ton Dollars	Difference per ton between price and value Dollars
Farm grains			
Barley, ground	53.00	57.18	+4.18
Corn, dent, ground	55.29	55.29	....
Oats, ground, not over 25% of concentrates	54.00	56.74	+2.74
Purchased concentrates			
Corn gluten feed	52.00	57.76	+5.76
Cottonseed meal 41% protein	66.00	65.06	—0.94
Distillers dried corn grains, without solubles	67.00	64.91	—2.09
Linseed meal, expeller or hydraulic process, 32% protein grade	72.00	66.40	—5.60
Molasses, cane, not over 10% of concentrates	47.00	45.82	—1.18
Soybean oil meal	75.00	75.00	....
Wheat bran	49.00	50.57	+1.57

Corn and soybean oil meal have remained at the same prices as in the first example, but the prices of barley and oats have declined. These grains are now more economical than corn for dairy cows. The price of corn gluten feed also has fallen, so that it is now the most economical protein supplement. Wheat bran is also low in price in comparison with other feeds. The other protein supplements are slightly less economical than corn gluten feed, wheat bran, and soybean oil meal. Molasses has declined slightly in price, but does not supply net energy as economically as do the grains.

With feeds at these changed prices, the cheapest concentrate mixture would have corn gluten feed as the only protein supplement. For cows of ordinary productive capacity, a mixture consisting of only ground barley, ground oats,

and corn gluten feed would be fairly satisfactory when fed along with good roughage. This is because the quality or kind of protein is not important for dairy cows that are fed plenty of good roughage. (1018)

However, most dairymen would prefer to use a concentrate mixture with greater variety and having some other protein supplement in addition to corn gluten feed. Let us therefore include some soybean oil meal in the mixture. It ranks next to corn gluten feed in economy at these prices, and it furnishes high-quality protein.

At these prices an excellent and economical mixture would be: Ground barley, 430 lbs.; ground oats, 200 lbs.; corn gluten feed, 200 lbs.; soybean oil meal, 70 lbs.; and wheat bran, 100 lbs.

These two examples well show that no particular combination of feeds should be used year after year, regardless of the changes in feed prices. On the contrary, the ration should be modified whenever necessary to adapt it to changed price conditions.

341. Relative economy of feeds when protein is cheap.—In the preceding examples protein-rich feeds have been more expensive than those rich in carbohydrates. Protein has therefore had an additional value beyond the amount of total digestible nutrients it furnishes. However, this is not always the case.

For example, in the cotton belt cottonseed meal is often lower in price per ton than farm grain. Also, in the alfalfa districts of the West alfalfa hay is frequently so cheap that it supplies total digestible nutrients at much less cost than do the grains or other carbohydrate-rich feeds. Even in the northeastern states, protein-rich concentrates are sometimes decidedly lower in price than the farm grains.

Under all such conditions, the values of various feeds will depend on the amounts of total digestible nutrients or of net energy that they furnish, and will not be affected by the amounts of digestible protein they contain. To compare feeds on the basis of net energy one should use the factors in the last column of figures in Appendix Table II. The method of using these factors is explained in the paragraphs that precede the table.

342. Limitations in comparisons based on digestible nutrients.—These methods of comparing the relative values of feed are much better adapted to comparisons of various concentrates than to comparisons of roughages. This is because such factors as palatability and the content of vitamins and minerals are often of great importance in determining the actual value of roughage.

Thus, a valuation on the basis of digestible nutrients, or on the basis of net energy, may not measure at all the actual difference in feeding value between well-cured, green-colored hay and hay that is weathered and bleached. The poor hay will, of course be considerably lower in digestible nutrients than the good hay. However, unless the stock get plenty of vitamin A value from some other source, the poor hay may be worth much less than is indicated by its content of digestible nutrients, due to the deficiency of this vitamin.

Also, one class of stock may have a much greater need than another class of animals for vitamins or minerals that the particular feed furnishes. For example, a limited amount of choice alfalfa or other legume hay has an especially high value, not measured by its content of digestible nutrients, as a source of vitamins A and D in the winter feeding of pigs in the northern states. Similarly, excellent hay is nearly indispensable in the raising of dairy calves. On the other hand, idle horses and beef breeding cows can be wintered successfully on roughage of rather inferior quality.

While comparisons of various roughages can be made by using the constants in Appendix Table II, it must be remembered that such a method of evaluation may have great shortcomings for these feeds. A much safer basis for valuing roughage is provided by the information presented in Part II concerning the value and usefulness of the various roughages for the different classes of stock.

Another limitation of this method of comparing the economy of various feeds

is that it does not take into consideration the *quality* of the protein in the different feeds.

Protein of high quality is especially important for swine, for poultry, and for dairy calves being raised on milk substitutes. Therefore, feeds that furnish protein of excellent quality, such as meat scrap, tankage, and fish meal, have a much higher relative value for these animals than for other classes of stock.

Other examples of the considerable differences in the relative values of certain feeds for various classes of stock have been given in Chapter III. (59) These differences show that, where the information is available, the results of feeding experiments are the most reliable guide to the value of any feed for a particular class of stock. Such information is given in the chapters of Part II.

II. Adapting Systems of Feeding to Local Conditions

343. Amount of protein to supply.—In the Morrison feeding standards a range is indicated in the amounts of protein which are advised for the various classes of farm animals. When protein-rich feeds cost but little or no more than those low in protein, it is well to feed as much protein as is indicated by the higher figures. On the other hand, when corn or the other grains are relatively cheap, it may be more economical to feed no more protein than is called for by the lower figures. Rarely is it advisable to feed decidedly less protein than shown in the lower figures.

Whether or not to add a protein supplement to certain rations will depend on the relative price of such supplements in comparison with the prices of the farm grains. For example, it is shown in Chapters XXVIII and XXX that corn and legume hay alone make a fairly well-balanced ration for fattening cattle or fattening lambs. However, the gains are usually slightly increased and a higher finish is secured when a small allowance of some suitable protein supplement is added to the ration. Whether such an addition will be profitable or not depends on the relative price of the supplement and on whether the market will pay an appreciably better price for the more highly-finished animal.

When protein-rich feeds supply nutrients more cheaply than those low in protein, as is often the case in the cotton belt and in the alfalfa districts of the West, it will be economical to feed more protein than the amounts stated in the standards.

344. Proportion of roughages to concentrates.—To meet the recommendations of the feeding standards for good milk cows and for fattening cattle and sheep, fairly liberal amounts of concentrates are required. This is because rations rich in digestible nutrients are needed for a high yield or for rapid fattening.

Unless grain or other concentrates are unusually expensive in comparison with roughages, it is generally advisable to feed such stock fully as much concentrates as called for by the higher set of total-digestible-nutrient recommendations in the feeding standards. On the other hand, when roughage is very cheap, it may be most profitable to feed only a small amount of concentrates.

Young cattle and lambs cannot be made fat enough to meet the demands of the large markets on harvested roughage alone, even if it is of excellent quality. On the other hand, little or no premium is paid on some local markets of the West for animals that have been well fattened by feeding them grain. Under such conditions it may not pay to feed any concentrates in addition to good hay or hay and silage.

With dairy cows much depends on the productive capacity of the cow. Except when concentrates are extremely high in price in comparison with roughages, a cow of good productive capacity will pay for at least a fair allowance of concentrates. On the contrary, the most economical rations for a low-producing cow, when concentrates are very high in price, may be legume hay and silage, with no concentrates whatsoever.

The feeding standards for growing cattle are based upon continuous thrifty

growth, and hence call for the feeding during winter of a small allowance of concentrates, unless a liberal amount of excellent roughage is fed. The breeder of pure-bred animals who wishes to develop the best there is in his young stock will feed sufficient concentrates to keep them growing rapidly. On the other hand, the western rancher may find it most profitable to carry young stock through the winter on roughage alone, or with but a very small allowance of concentrates. Thus fed, they will gain in frame and, though losing in flesh, will be thrifty enough in the spring to make good gains on the cheap pasturage.

It is a matter of great financial importance in stock farming to make a wise decision concerning the amounts of concentrates to feed the different classes of stock under varied conditions. This matter is therefore given special consideration in Part III of this volume.

345. When roughage is scarce.—Occasionally there is a serious shortage of roughage in some part of the country, because of severe drouth. Hay and other roughage may then be so high in price that digestible nutrients in roughages will be much more expensive than digestible nutrients in grain and other concentrates.

Under such conditions, it is most economical to increase the proportion of concentrates somewhat and to feed no more roughage than is necessary to provide adequate bulk in the ration and a sufficient supply of vitamins.

However, enough roughage must be fed to meet the needs of the particular animals. It is shown in Chapter XXV that in experiments in which dairy cows have been fed a very small amount of roughage, especially chopped or ground hay, they have often gone off feed, and the milk yield and fat percentage have dropped greatly.

BEEF STEERS ON FULL-FEED IN A CORN-BELT FEED LOT

On this corn-belt farm practically all the land is suitable for tillage and corn is the main crop. During the winter, western feeder cattle are fattened in dry lot on a full feed of corn grain, plus corn silage, legume hay, and a small allowance of protein supplement. A maximum amount of corn grain is thus utilized on the farm.

346. Finish animals to meet demands of the market.—The wise stockman will keep in close touch with the demands of the market and adjust his feeding operations accordingly. If the market pays a sufficient premium for thoroughly-fattened animals, he will fat-

ten his stock well before marketing them. On the other hand, on local markets which pay no more for a well-finished carcass than for one carrying less fat, it will not pay to prolong the fattening period or to feed as much concentrates as are necessary to make the animals thoroughly fat.

347. Seasonal trends in prices of feeds.—A stockman who is a close observer of the usual trends in prices of grains and other feeds can sometimes save money by buying a supply at the time of year when the particular feed is generally lower in price than at other seasons.

For example, the grains are generally lower in price at harvest time, when the marketings are heaviest.[3] The price tends to rise during the year, until the effects of the new crop begin to be felt. Wheat bran is apt to be lower in price in the fall than at other seasons.

348. Efficiency in the use of labor.—Since man labor forms a considerable part of the costs in livestock production, every effort should be made to use labor as efficiently as is possible. As is shown in the chapters of Part III, the number of hours of labor spent in feeding and caring for stock can often be greatly reduced by careful planning. (1101)

To save labor, stables and feed lots should be arranged so that the minimum amount of labor and walking about is required. Much labor can be saved by convenient tools and equipment, such as feed carts and a water system in the barn with individual drinking cups for stall-fed animals. Much time in caring for dairy cows can be saved by the adoption of the rapid-milking method. (**1093**)

BEEF HERD ON PASTURE UNSUITED FOR TILLAGE

On this farm there is considerable land which is too rough for tillage. This provides pasturage for a breeding herd of beef cattle. The cattle are wintered on hay and other roughage, and grain is used only for fattening the young cattle for market.

349. Adapt type of farming to local conditions.—It is outside the field of this volume to discuss in detail the many factors which the stockman should take into consideration in deciding the type of livestock farming in which to engage and the systems and methods to follow. The farm operations and practices should always be suited to local conditions, and should be based upon the prices of land and labor, the nearness to market, and the available crops.

For example, the beef producer on high-priced land in the eastern part of

the corn belt will often crowd his calves to rapid growth on a heavy allowance of grain and fatten them as baby beeves. Perhaps he will raise no cattle, but fatten feeder steers from the western ranges on a liberal allowance of corn.

On the other hand, in the West where pasture is cheap compared with grain, the rancher will usually follow a much less intensive system of beef production. Even during the winter his breeding herd will be maintained as largely as possible on the range and will be fed harvested feeds only when the range forage is covered by snow. Instead of fattening his steers for market, the rancher will commonly sell them in the fall as feeder cattle, to be shipped to the districts where grain is cheaper. When he does fatten cattle, he will feed them chiefly on roughage, with only a limited amount of grain.

Dairymen producing market milk on high-priced land near large cities often use only a small acreage of land for pasture, but instead rely largely on corn silage or soiling crops for roughage during the summer. They often buy most of the concentrates for their cows, including grain as well as protein supplements. They do this because grain can be grown on land farther from market and shipped in at a lower price than the cost of raising it on their own farms. Sometimes they even buy a considerable part of the hay they feed in winter.

Such a system would be decidedly uneconomical for the dairyman remote from the large markets, whose milk is used in the manufacture of butter or cheese. With him land is less expensive than labor. He must therefore adopt a less intensive system of dairying, in which the herd is maintained chiefly on pasture in summer, and in which just as much as possible of the feed for the remainder of the year is produced on the farm.

III. Economy of Food Production by Various Animals

350. Proportion of animal food in the human diet.—In areas of the world where the density of population presses most upon the food supply, foods of animal origin form but a small part of the human diet.[4] In such regions, people must eat all or nearly all the edible food produced on the cultivated fields, and farm animals can have only the forage or other feed that cannot be consumed by man. This is because there is a large loss of energy or heat value in converting into human food the grain or other feed eaten by livestock.

In such parts of the world but few farm animals can be kept in cultivated areas for the primary purpose of producing food for man. Animals are kept for draft or work, perhaps also producing a very limited amount of milk for humans, and they are eaten only when they are no longer efficient work animals. Areas that are unsuited to crop production are grazed by sheep, goats, or cattle, which contribute to the small supply of foods of animal origin. Swine and poultry are kept chiefly as scavengers, living mainly on garbage and other waste products.

According to estimates by Pearson and Harper, grain and grain products make up about 73 per cent, on the dry basis, of the total food consumed by the world's population, and all animal products about 9 per cent.[5] Vegetables and fruits form 12 per cent of the world's human food, and sugar 6 per cent. Included in the animal products are milk and milk products, estimated at 5 per cent on the dry basis, meat at 4 per cent, and fish and eggs each at less than one-half per cent.

The proportion of the total human food that comes from animal sources differs greatly in various regions. In North America it is 25 per cent and in Oceania (over three-fourths of whose population is in Australia and New Zealand) even higher, being 36 per cent. At the other extreme, in Asia foods of animal origin form only 3 per cent of the human diet and in Africa but 4 per cent.

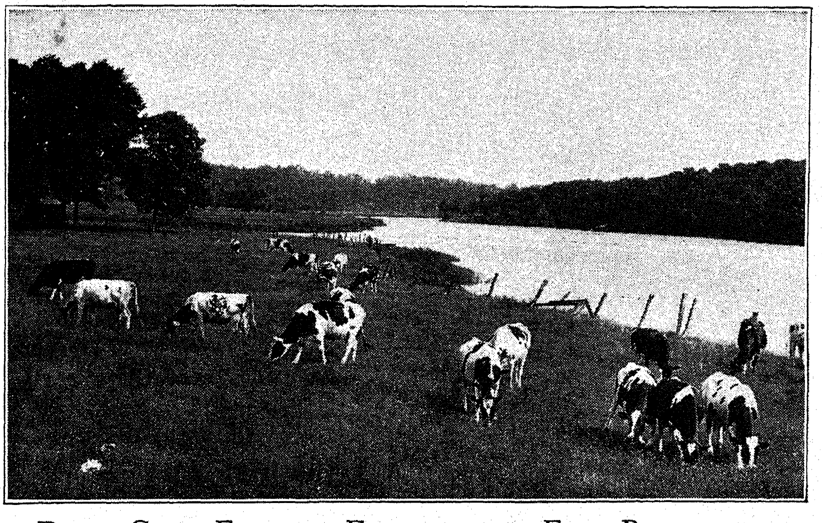
351. Relative efficiency of various animals on energy basis.—Such data lead naturally to a consideration of the relative efficiency of the various farm animals in producing human food, and to a

discussion of the special values in the human diet of foods of animal origin.

Let us first consider the efficiency with which various animals convert the gross energy of the feed they consume into energy in human food. This is the simplest basis for comparison, but all will agree that it is an inadequate measure of the efficiency of farm animals. We do not eat animal products primarily as a source of energy, for we can get energy at a fraction of the cost by eating grain products or such foods as potatoes.

Maynard has estimated that the following average percentages of the gross energy in the feed eaten by various kinds of animals are converted into human food: Pork, 20 per cent; milk (dairy cows), 15 per cent; eggs, 7 per cent; poultry meat, 5 per cent; beef, 4 per cent; lamb, 4 per cent.[5]

The estimates were based on somewhat better than average levels of production. For milk production the estimates were based on an annual yield per cow of 7,000 to 8,000 lbs., which is considerably above the United States average. The estimates for pork were for the period from weaning to slaughter at approximately 230 lbs. live weight. For beef and lamb the estimates were limited to the fattening period in the feed lot because of the impossibility of measuring the feed intake from pasture or range. No credit was given in the estimate for the wool produced by lambs. For egg production the estimate was for an annual production of about 150 eggs per bird. Since these estimates were made, progressive farmers have improved the efficiency of their pork production somewhat by the use of antibiotic and vitamin B_{12} supplements, and the efficiency of poultry meat has been increased by the use of these supplements and also by feeding high-energy rations.



DAIRY COWS EXCEL IN EFFICIENCY OF FOOD PRODUCTION

When due consideration is given to the richness of milk in high-quality protein, calcium, and vitamins, dairy cows are decidedly more efficient than other animals in producing human food.

In these estimates and also in others that have been made, pork production and milk production rank far ahead of other types of animal production, when measured by the percentage of the gross energy of the feed which is converted into edible human food.

In comparing the efficiency of pork production and of milk production, we

must bear in mind that under conditions such as in the United States hogs live chiefly on grain and other concentrated feeds which are high in digestibility and consequently high in net-energy value. On the other hand, only about one-third of the dry weight of the feed of dairy cows usually consists of grain and other concentrates. Two-thirds comes from pasturage, hay, silage, and other roughages, all of which are much lower in digestibility and in net-energy value than the grains.

Measured on the basis of the efficiency with which they convert either digestible nutrients or net energy into human food, dairy cows would rank somewhat above swine. Also, measured on the basis of the calories of human food produced per acre of crop fed, milk production would rank slightly above pork production.

It must be borne in mind that these estimates of the efficiency of milk production are based upon the human consumption of all the food value in milk. When butter is eaten and the skimmilk is used for animal feeding, the efficiency of human food production is, of course, decidedly lower.

In all comparisons of the efficiency of the production of human food by the different classes of farm animals, certain facts must always be remembered. Swine and poultry are direct competitors with man for food, because under our conditions they live chiefly on grain.

In this country dairy cows compete with man for food to a much greater extent than do beef cattle or sheep. This is because our dairying is located almost entirely on land that could be used for the direct production of human food. While dairy cows on many farms utilize pasturage on some areas that could not readily be tilled, such forage forms but a small part of the total feed eaten by our dairy cows.

On the other hand, our beef cattle and sheep are mostly raised on the western ranges or on other grazing land that is unsuited to tillage under present conditions. Here they convert forage that would otherwise be wasted into valuable human food and other products, needed by man, such as wool and hides. Except for the very limited amounts of harvested roughage and of concentrates which may be needed during the winter period, range beef cattle, sheep, and Angora goats do not compete with man for food, or even with dairy cows, swine, and poultry.

352. Relative economy considering other factors.—The chief value of most foods of animal origin lies not in the energy they furnish, but in their high-quality protein and in their content of minerals and vitamins. It is difficult to take all these nutrients into consideration in comparing the economy of various food sources. However, protein can and should certainly be considered, along with energy.

To take both energy and protein into consideration, Jennings has estimated the feed units required by the various farm animals to produce what he calls "a calorie-plus-protein index."[6] In this index the production of 0.15 lb. of protein (a day's allowance for an average person) is given the same weight as the production of 2,600 Calories (which is the daily energy allowance for an average person).

The feed units are approximate estimates of the value of various feeds in comparison with 1 lb. of corn grain as the standard. Hay and other roughages are valued approximately in proportion to their net-energy values. Protein supplements, such as soybean oil meal, are given a considerably higher value than corn grain, although their net-energy values are usually lower, instead of higher, than that of corn grain. These higher values are given to protein supplements because of the higher total feeding value of a protein supplement when properly used to balance a ration low in protein.

Measured on this basis, he estimates that the following amounts of feed units are required for the production of a calorie-plus-protein index of 1.0: Milk production, 6.5; pork production, 9.2; turkey meat, 9.7; eggs, 10.7; chicken meat, 12.0; beef, 41.3; and lamb, 51.7.

These estimates are for average conditions.

It should be noted that on this basis milk production is decidedly more efficient than pork production. Turkeys are rated nearly equal to pigs in efficiency of meat production, and ahead of the efficiency of egg production.

Considering total feed consumed, beef cattle and sheep fall far below the other farm animals in efficiency. However, Jennings also gives similar estimates of the grain and other concentrates, not including pasture, hay, and other roughage, required by the various farm animals to produce a calorie-plus-protein index of 1.0.

On this basis, dairy cows lead, with a requirement of only 1.6 feed units. For other types of livestock production the following amounts of feed units are required in grain and other concentrates: Lamb, 3.2; pork, 8.6; beef, 8.8; turkey meat, 8.8; eggs, 10.1; and chicken meat, 10.9 feed units.

353. Importance of animal foods in the human diet.—Among foods of animal origin, milk production not only ranks first in efficiency of production when both energy and protein are considered, but it also is of especial value in the diet as a source of calcium and vitamin A. Both of these nutrients are needed in very large amounts by children and by pregnant and nursing mothers. Milk is likewise rich in phosphorus, but a deficiency of phosphorus occurs in human diets much less frequently than a lack of calcium or of vitamin A.

Maynard emphasizes that since calcium cannot be supplied adequately by any combination of vegetable foods which our people can be expected to eat, the high content of calcium in milk is of especial importance. One quart of milk a day supplies the full allowance of calcium recommended by the Food and Nutrition Board for a growing child, except during adolescence, and more than is needed by the adult, except for expectant and nursing mothers. It would take 45 eggs to supply as much calcium as is furnished by a quart of milk.

The importance of milk and of all dairy products which include the butterfat, as sources of vitamin A in the human diet is so generally recognized that it needs no discussion. Milk is also rich in riboflavin, and it is a good source of vitamin B_{12} and other B-complex vitamins.

Eggs are important sources of vitamin A value, being three times as rich as milk per unit of total energy. They are also an important source of calcium, are the richest of all animal foods in iron, are high in riboflavin, and are the only important source of vitamin D among natural human foods.

In addition to its high value as a source of excellent quality protein, meat is important in furnishing iron and certain B-complex vitamins, especially niacin. Pork ranks high in thiamine content, and it is estimated that nearly half of the thiamine in the average diet in this country is supplied by animal products.

An important point is that ruminants do not apparently require the B-complex vitamins in their feed, because these vitamins are synthesized in the fermentations which occur normally in the rumen, or paunch. On the other hand, pigs and chickens, like humans, must have an adequate supply in their food.

An exceedingly important quality of most foods of animal origin is their high palatability. Not only do they taste good in themselves, but they also greatly increase the acceptability of other foods. The universal desire of our people for a liberal amount of meat, when they can afford it, was dramatically shown in wartime. When meat supplies became scanty, buyers formed long queues and dissatisfaction and complaint were widespread.

Considering all factors, milk production easily ranks first in importance and efficiency of production, among foods of animal origin. For this reason, every effort was made in Great Britain and other European countries during the war years to keep milk production as near the normal level as possible, and

to restrict severely the concentrated feeds allotted for other classes of farm animals.

From the energy standpoint, pigs would rank next, but considering all factors, second place in efficiency should probably be given to egg production.

From the standpoint of national food economy, the production of beef and lamb also ranks very high, insofar as the meat is produced largely from forage which would not otherwise be utilized.

In considering the place of animal products in our economy, we must bear in mind that farm animals furnish other products. The farm manure they produce is highly important in the maintenance of the fertility of our farms. Other important products, of course, are wool, mohair, hides, by-products for animal feed, and an array of special packing-house by-products.

354. Increasing the production of foods of animal origin.—In considering the place of animal products in our national economy, we must give attention to the possibilities of increasing the supply of these products as our population grows, without decreasing the yield of crops grown for human food.

First of all, the amount and the efficiency of animal production could be very considerably increased if all farmers adopted and carried out the methods now used by the most efficient third. For example, the average milk yield per cow could be increased from the present national average of about 5,630 lbs. to the average in Dairy Herd Improvement Association herds throughout the country, which was 9,363 lbs. in 1954. All that is needed for such an increase is the putting into practice by all farmers of the methods and practices that are now well known, and are practiced by the more progressive farmers. These include well-planned crop rotations, proper fertilization, and good soil management, as well as efficient feeding and breeding of dairy cattle.

To reach the goal of high average milk production, cows must, first of all, be provided with a more abundant supply of roughage of higher quality. This means better pasture, such as that furnished by combinations including such efficient and nutritious pasture crops as alfalfa, Ladino clover, bromegrass, and lespedeza. It also means the production of better hay, curing it efficiently, and feeding it in abundance. In most dairy districts, it will moreover mean the providing of more high-quality silage from corn or the sorghums, or from hay crops ensiled by special methods.

By supplying cows with an abundance of such roughage throughout the year, the amounts of grain and other concentrates required to maintain high milk production can be reduced decidedly. Yet, under our usual conditions, it is essential that good dairy cows be fed sufficient concentrates for a high yield. When they are fed roughage alone, even of excellent quality, the milk yield is greatly reduced.

Such a program of abundant and better roughage for dairy herds should increase, rather than decrease, the supply of grain for human consumption. The fields used in rotation for grain production, with legumes in the rotation, will produce much higher yields than under less efficient cropping methods. Actually, a smaller acreage per cow may be needed to supply ample high-quality pasture and harvested forage than is now needed to furnish a rather scanty amount of mediocre roughage.

It is important to note that the improved roughage feeding of dairy cows, which will increase their production, will also increase the vitamin-A value of milk and butter markedly. In particular, an abundance of high-quality hay and especially of hay-crop silage will maintain a high vitamin-A value in milk in winter, when otherwise it has a lower amount.

The rapid development of artificial insemination of dairy cows has made possible a decided increase in the productive capacity of our cows. Through this means a dairyman can at moderate cost have his cows bred to a bred-for-production sire of a transmitting ability

that has not hitherto been generally available to farmers who do not have large herds.

As our population increases and we need more food, the production of beef and lamb can be considerably increased by converting some of our semi-abandoned hill lands into first-class pastures. There are considerable such areas in the northeastern states and in many sections of the South. Large areas of the cut-over lands of our northern states are also yet undeveloped.

These are but examples of the manner in which the production of foods of animal origin can be increased as our population grows. Similarly, our production of other foods can be greatly increased through fuller utilization of our land resources, improved varieties of crops, increased use of fertilizers, and better soil management.

Even with a considerably greater population, our present dietary standards can not only be maintained but even materially improved, with resulting benefit to the health of our people.

QUESTIONS

1. Using local prices for feeds, see if you can find instances where the market price of a feed does not represent its actual feeding value compared with other feeds which are available.
2. What difficulties are there in comparing the relative economy of various feeds on the basis of the cost per pound of total digestible nutrients and the cost per pound of digestible protein?
3. How is the relative value of a feed determined by the Petersen method?
4. Find the local prices of at least 3 farm grains and 5 protein supplements suitable for dairy cows. Then determine, by using the Petersen method, which of these feeds are actually the cheapest. Finally, work out the most economical concentrate mixture you can that will supply 16.0 per cent digestible protein and be excellent for dairy cows.
5. On what basis should feeds be compared when protein-rich feeds cost no more than those low in protein?
6. Why are comparisons of the values of various roughages, based solely on digestible nutrients or net energy, less reliable than similar comparisons of concentrates?
7. How would you adapt the amount of protein in the ration to local conditions?
8. When would you feed less concentrates than called for in the feeding standards?
9. Under what conditions are beef calves fattened for baby beef?
10. Discuss other ways in which you would adapt the type of farming to local conditions.
11. Compare the proportions of the total human food in various parts of the world which come from animal sources.
12. Discuss the relative efficiency on the energy basis of various farm animals in producing human food.
13. Compare the efficiency of various farm animals in producing human food, when both energy and protein are considered.
14. Discuss the importance of animal foods in the human diet.
15. How can the supply of foods of animal origin be increased in this country, without reducing the production of crops grown for human food?

PART II

FEEDING STUFFS

CHAPTER XIII

PASTURE AND OTHER FORAGE

I. FACTORS AFFECTING THE VALUE OF FORAGE

355. Importance of pasture and other forage.—Pasture and other forages are considered first in this volume, among all the different feeds, because of their outstanding importance in livestock production. For all classes of stock except swine and poultry, good forage, including abundant pasture, is the foundation of efficient production. Even for swine and poultry, high-quality forage is very important as a source of vitamins, minerals, and protein.

This country has witnessed a striking trend toward "grassland farming" during recent years. This has come about because our farmers have come to appreciate more fully the economy of excellent pasture and hay crops in livestock production, and also their importance in maintaining soil fertility and preventing water and wind erosion. This great change in our agriculture has resulted because of the extensive research on forage production by the experiment stations and the United States Department of Agriculture, and the effective extension work which has convinced farmers of the value to them of the new methods of producing more and far better forage.

The importance of forage crops in the United States is shown by the fact that forage, including pasture, hay, silage, and stover, forms about 55 per cent of all feed consumed by our livestock.[1] For dairy cattle, 74 per cent of the feed comes from forage; for beef cattle, 82 per cent; for sheep and goats, 94 per cent; and for horses and mules, 68 per cent. Our swine and poultry are fed mostly concentrates, forage making up only 3 per cent of the feed for swine and 5 per cent for poultry. It is shown in Chapter XXXV that the cost of producing pork can generally be reduced appreciably by making more use of first-class pasture. Also, except in intensive, large-scale poultry production, excellent pasture reduces costs.

Commonly, cattle, sheep, and horses are provided with all the forage they will consume, and then are fed in addition whatever grain and other concentrates they need to meet their requirements.

Before discussing the value and use of the various forage crops in the following chapters, it is important to consider the different methods of utilizing forage, and the factors that affect its nutritive value.

356. Abundant excellent forage increases profits.—That an abundant supply of excellent forage increases profits in livestock farming is well shown by a recent cost study on dairy farms in southern Michigan.[2] On the farms where the quality of roughage was excellent throughout the year, the annual return over feed cost per cow was $65 more than on the farms where the roughage was graded poor. Though the dairymen having excellent roughage fed 1,307 lbs. less concentrates per cow a year, their average milk yield per cow was higher than on the farms with poor roughage. An important fact was that the feed cost of producing each 100 lbs. of milk was

reduced 46 cents by providing plenty of excellent roughage.

357. Economy of pasture.—Good pasture generally supplies the most economical feed for cattle, sheep, and horses during the growing season. Even for swine, it is an important means of reducing the cost of feeding. This is in spite of the fact, pointed out later in this chapter, that the yields of nutrients are usually less when grasses and other hay crops are pastured, in comparison with their yields for hay. The difference in yield is much more than offset by the greater expense for labor, seed, and machinery in planting, tilling, harvesting, and feeding forage crops.

The economy of pasture is well shown in studies conducted by the United States Department of Agriculture in 7 dairy districts of this country.[3] In these areas pasturage furnished nearly one-third of the total nutrients consumed by the cows during the year, but the cost of the pasturage was only one-seventh of the total annual feed cost. In similar studies on 478 corn-belt beef farms, the breeding cows obtained practically all their feed from pasture for 200 days of the year. While the pastures furnished a little more than one-half the total feed for the whole year, the cost of pasture was only one-third of the annual feed bill.

On dairy farms in southern Indiana pasture furnished total digestible nutrients at 27 per cent of the cost of harvested feeds, although each acre of pasture produced only one-half as much actual feed per acre as corn or legume hay grown on the same land.[4] From cost studies on New York dairy farms it was estimated that the cost of total digestible nutrients from pasture was less than one-sixth as much as from concentrates, about one-half as much as from hay, and one-third as much as from silage.[5]

The effectiveness of pasture in reducing the cost of milk production is shown by studies on farms in various areas of New York.[6] The average total cost of producing milk on these farms during the grazing season was only 55 per cent as great per 100 lbs. as it was during the winter barn-feeding season.

When a well-adapted mixture of pasture grasses and legumes is grown on fertilized land and grazed rotationally, the yield of nutrients per acre may be nearly as great as from alfalfa hay on similar land. For example, in Maryland tests well-fertilized pasture grazed in rotation yielded an average of 2,567 lbs. of total digestible nutrients per acre during the season.[7] Alfalfa hay, grown on similar fertilized land, yielded 2.8 tons of hay per acre containing 2,926 lbs. of total digestible nutrients. Unfertilized pasture on the same sort of land, which was grazed continuously instead of rotationally, yielded only 1,552 lbs. of total digestible nutrients per acre.

358. Nutrients at different stages.—Many stockmen do not fully realize the great differences there are in nutritive value between young, immature forage crops and the same plants when they are mature or even at the usual hay stage of growth. These wide differences are shown in the data given in Appendix Tables I, II, IV, and V for different forage crops at various stages of maturity.

First of all, young plants are very much richer in protein, on the dry basis, than the same plants at later stages of growth. Thus, in the northern states young pasture grass that is growing actively usually contains 16 per cent or more of protein when dried to a hay basis. This is even more protein than there is in alfalfa hay of good quality. Young legumes, such as alfalfa and clover, are even richer than young grass in protein. On the other hand, when pasture plants become mature and weathered, the protein content may fall to a very low level.

Many farmers fail to take advantage of the fact that stock on good, actively-growing pasture receive a liberal supply of protein. For example, dairy cows on such pasture are often fed a concentrate or grain mixture containing much more protein than necessary. This does not increase their production, and it is usually decidedly uneconomical. **(1080)** Similarly, beef cattle being fattened on first-rate pasture are sometimes fed con-

siderably more protein supplement than is needed.

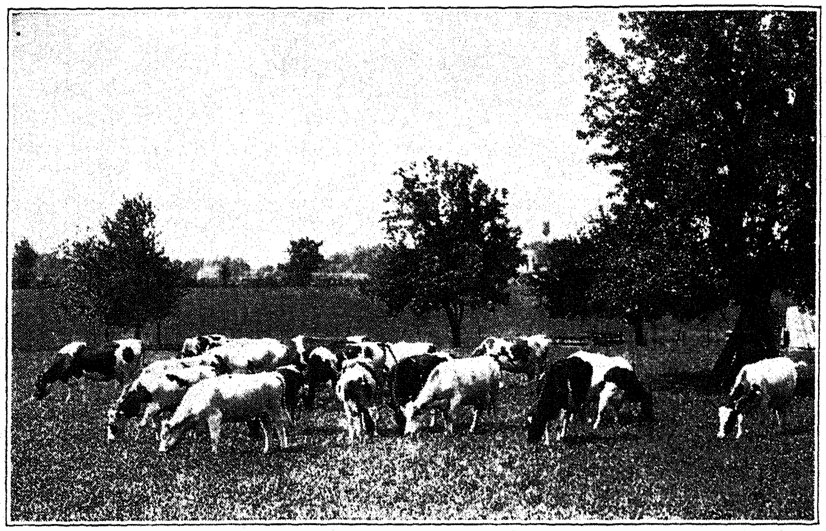
The second great difference between young plants and those that are more mature is that the young plants are soft and tender and have much less fiber and less lignin, on the dry basis, than at later stages of growth. They are therefore more digestible than hay cut at the usual time. When dried to a hay basis, mixed pasture grass and clover from fertile, closely-grazed pasture supplies 66.7 per cent total digestible nutrients, in comparison with 51.0 per cent for clover and timothy hay of good quality, cut at the usual stage of maturity. There is probably an even greater difference in net-energy value between young grass or clover and hay made from the same crop at the usual stage of growth.

When grass becomes mature, the digestibility and nutritive value are decreased still more. If it is then weathered by exposure, it will resemble a rather poor grade of straw in composition and value. The more digestible and valuable nutrients will have been largely lost by leaching or by the shattering of leaves and other finer parts.

In addition to the richness in protein and the high digestibility of young forage plants, they contain much more phosphorus, on the dry basis, than at later stages of growth and are also somewhat higher in calcium. Moreover, young forage plants are much richer in vitamins, especially in vitamin-A value.

359. Protein content at various stages of growth.—Many studies have been conducted to find the content of protein and other nutrients in various grasses and other forage crops at different stages of growth.[8] These investigations have shown that under such climatic conditions as those in the northern part of the United States, the best pasture grasses will contain, before heading out, 16 to 20 per cent of protein, on the dry basis. At pasture stages of growth, alfalfa, red clover, or Ladino clover will have, on the dry basis, 20 to 25 per cent of protein or even more.

The protein percentage in the grasses decreases greatly when they head out, largely because of the accumulation of carbohydrates. Also, after grass has headed out, there is a much smaller proportion of leaves in the plants. Grass hay,



IMMATURE, ACTIVELY-GROWING GRASS IS RICH IN PROTEIN

On excellent, actively-growing grass pasture, such as this, dairy cows do not need a concentrate mixture high in protein, for the young grass is rich in protein.

cut at the usual stages of maturity, will generally have only 6 to 9 per cent of protein, on the dry basis, and the later it is cut, the lower will be the protein content.

When grasses become mature and especially when they are weathered by exposure, the protein may fall to only 3 per cent or less, on the dry basis. Stock grazing on such grass will therefore suffer from a deficiency of protein, unless they are fed a protein supplement.

The protein percentage of legume forage crops also decreases as they advance in stage of growth, but to a much less extent than in the case of the grasses. For example, alfalfa hay cut before bloom has an average of 18.6 per cent protein, and alfalfa hay harvested after bloom still has an average of 12.9 per cent protein. (Appendix Table I.)

Under such climatic conditions as in the southern states, grasses at the pasture stage seem generally to have a much lower percentage of protein than do grasses at the same stage in a cooler climate. This is apparently the case except when heavy applications of nitrogen fertilizer are made, or on soils very high in nitrogen, such as the peat soils of the Florida Everglades district.

It will be noted in Appendix Table I, that mixed pasture grasses and legumes from fertile pasture in the southern states have an average of only 3.8 per cent protein on the fresh basis, equivalent to 15.1 per cent on the dry basis. In other districts of the United States the protein content of mixed pasture grasses and legumes from closely grazed, fertile pasture averages 22.7 per cent, on the dry basis.

LATER, THE GRASSES AND CEREALS ARE LOWER IN PROTEIN

When the grasses and cereals have headed out, the percentage of protein, on the dry basis, is much lower than at early stages of growth. Hereford cattle on rye pasture which has headed out.

360. Digestible nutrients at various stages.—Numerous experiments have shown that young pasture forage is much more digestible than the same plants at a later stage of growth. The difference is especially great when the plants become mature and will be still greater if they are weathered by exposure.

To a considerable extent the decrease in digestibility as plants become more mature is due to the increase in lignin.[9] Lignin, which is classed with the carbohydrates, although not a true carbohydrate, has a very low digestibility,

even by ruminants or horses, and other animals can digest practically none of it. (**11**) Its nutritive value is therefore much less than that of cellulose. The digestibility of older plants is also reduced because the cell walls, especially of the stems, become lignified, or encrusted with lignin. This decreases the digestibility of the nutrients which are enclosed within the cell walls.

The composition and digestible nutrients in various important pasture and hay crops at different stages of growth are shown in Appendix Table I. For example, timothy hay, cut in early bloom, has 4.2 per cent digestible protein and 51.7 per cent total digestible nutrients, on the average; that cut in full bloom, 3.2 per cent digestible protein and 51.1 per cent total digestible nutrients; and that cut at the late seed stage, only 1.9 per cent digestible protein and 41.9 per cent total digestible nutrients. Timothy hay cut at the latter stage is no higher in digestible nutrients than oat straw, although it has somewhat more digestible protein.

361. Phosphorus and calcium at various stages.—Young grasses or legumes on land well supplied with phosphorus have a good content of phosphorus, usually containing 0.25 per cent or more of it, on the dry basis. The percentage of phosphorus decreases somewhat as the plants become older, but until they are nearly mature there will generally be plenty for livestock. If the forage becomes mature and weathered, the phosphorus content falls greatly. Even where there is no phosphorus deficiency in the soil, such forage may not supply enough to meet the requirements of animals pastured on it.

Where the soil is slightly deficient in phosphorus, pasture plants may furnish enough phosphorus during active growth, but there may be a serious deficiency when the plants are mature and weathered. For example, on a New Mexico range pasture where there was a moderate deficiency of phosphorus, grasses had over 0.10 per cent of phosphorus on the dry basis during active growth.[10] When the forage became mature and weathered during the winter, it had only about one-half as much phosphorus, which was much less than stock need for health.

The percentage of calcium, on the dry basis, in grasses and other forage plants decreases somewhat as growth advances and carbohydrates are accumulated in the plants. However, the change is much less than in the content of phosphorus. Even mature and weathered grass will generally supply enough calcium for grazing animals, unless the soil is extremely deficient in the mineral.

362. Vitamin content at various stages.—One of the most important facts in livestock feeding is that all actively-growing green parts of plants have a very high vitamin-A value, because of their richness in carotene. This is shown by the analyses summarized in Appendix Table V. Such forage is also rich in most of the B-complex vitamins, in vitamin E, in ascorbic acid, and in certain unknown vitamins that are required by animals. (Chapter VII.) Good pasture therefore abundantly takes care of the vitamin needs of farm animals.

It has been pointed out previously that green plants contain little or no vitamin D. However, this is generally not of importance for stock on pasture, because their vitamin D requirements are met through the effect of the ultra-violet rays in sunlight. (**201**)

The content of vitamins, especially of carotene, decreases as plant growth advances.[11] Early-cut hay is therefore much richer in vitamins than late-cut hay, if it is equally well cured. When pasture plants mature and dry, the carotene is lost rapidly. Practically all the carotene disappears from most grasses and other pasture plants when they become mature and weathered, but if the lower parts of the stems or some of the leaves remain green, a small amount of carotene will be retained. (**196**)

363. Selective grazing.—If there is plenty of forage in a pasture, livestock tend to select the leaves and finer parts of the stems, which are more tender and more nutritious, and eat less of the coarser stemmy parts. The com-

position of the forage actually eaten may therefore differ appreciably from that of the entire plants, including all the stems.

In recent New York studies with cattle on rather mature grass pasture, they digested 60 per cent or more of the dry matter in the forage eaten.[12] However, when the entire plants were cut and fed to the cattle, only 45 per cent of the dry matter was digested. In the case of very young and palatable pasturage, there is much less selectivity in grazing.

364. Effect of rate of growth and season of year.—Grass is generally rich in protein, on the dry basis, and otherwise of high nutritive value, as long as it is kept growing actively and is prevented from heading out. Proper fertilization and good pasture management are therefore important to produce pasturage of high value throughout as much of the season as is possible.

The grass will usually be somewhat richer in protein in spring and early summer when the growth is most rapid, than later in summer. If growth is decidedly checked in midsummer by drouth, by a lack of available plant food, or by hot weather, the protein content and the digestibility will be decidedly lower than that of grass at the same stage of maturity earlier in the season. Often such pasturage will contain 12 per cent or less of protein, on the dry basis, in comparison with 16 per cent or more for rapidly-growing grass.

If the grass resumes rapid growth in the autumn after fall rains come, the protein content may be nearly as high as early in the season. In case the grass is allowed to head out and go to seed at any time, the protein content will be relatively low.

365. Differences in effects on various crops.—There are marked differences between various kinds of pasture and hay plants in the rate of changes as growth advances. Among the grasses, bromegrass retains its palatability and nutritive value over a much longer period than most grasses. The protein and carotene content fall less rapidly, and there is less increase in fiber. Sudan grass also retains a high value over a long season. At the other extreme are such grasses as orchard grass and reed canary grass, which are readily eaten by stock when young but rapidly become woody and unpalatable.

Among the grasses in the western range states, crested wheat grass starts growth earlier in the season than most of the native grasses, but does not retain its palatability and nutritive value well after the blossom stage. To make good hay, such grasses as orchard grass or crested wheat grass must therefore be cut early.

Most legume pasture and hay crops retain their palatability and nutritive value at late stages of growth somewhat better than the majority of the grasses. An exception is lespedeza sericea, which is unpalatable to stock except when very young. It soon becomes distasteful, because of a considerable accumulation in the plants of tannin, which is bitter.

366. Certain forage crops richer in nutrients when mature.—The only exceptions to the general rule that immature plants are lower in fiber and higher in total digestible nutrients, on the dry basis, than when mature, are such crops as corn, the small grains, the sorghums, and soybeans. In these crops large amounts of highly digestible nutrients are stored in the seeds as they approach maturity. The percentages of total digestible nutrients are therefore commonly higher when the seed has fully developed in such crops (considering both the seed and the stover or straw), than at an earlier stage.

367. Immature grass not a concentrate.—Occasionally, some persons become so enthusiastic about the nutritive merits of first-class pasture that they conclude it is fully the equivalent of a protein-rich concentrate. This is a considerable exaggeration.

Good pasture forage may be fully as rich in protein, on the dry basis, as wheat bran or wheat middlings, and even as rich as corn gluten feed or brewers' dried grains. In vitamin content such forage is unexcelled. However, in two

important respects the best of immature forage differs markedly from a high-grade concentrate. This is in the percentage of fiber, and consequently in the content of total digestible nutrients or net energy.

For example, corn grain has only about 2 per cent fiber, while young pasture forage will usually have 18 to 20 per cent, if dried to the same dry matter content. Because of the large difference in fiber, pasture forage furnishes considerably less total digestible nutrients, on the dry basis, than do high grade concentrates.

In content of total digestible nutrients young pasture forage of good quality is about half way between high-grade concentrates and good hay. High-grade concentrates usually have 75 per cent or more of total digestible nutrients; good hay has about 50 per cent; and first-rate pasture forage 60 to 67 per cent, when dried to a hay basis. There is an even greater difference in the net energy value of pasture forage and of high-grade concentrates.

By providing dairy cows, beef cattle, and sheep with an abundance of good pasture throughout the growing season, and with plenty of first-rate hay or hay and silage in winter, the amount of concentrates needed for good production can be considerably reduced. However, good pasture and high-quality hay cannot fully take the place of concentrates.

Dairy cows of high productive capacity need some concentrates in addition to excellent pasture and other high-quality roughage, or their milk yield will be much reduced. (**1023**) This is well shown by Montana tests in which cows that had been fed a liberal amount of concentrates the previous year, were then fed for a year on only roughage of the very best quality.[13] During the grazing season this was pasture on irrigated land, and in winter either hay or silage made from immature pasture forage. On roughage alone the cows yielded only 63 per cent as much milk, on the mature-equivalent basis, as during the previous year when they had been fed concentrates in addition.

Similarly, concentrates are needed in addition to good pasture to produce a good degree of fatness, or finish, on young beef cattle. In the case of pigs and poultry, the difference in the effects of young forage plants and of concentrates is still greater. This is because their digestive tracts do not enable them to eat a great amount of roughage. Even with the best of pasture as the only feed, pigs will not make normal growth, to say nothing about fattening. Though good pasture is important in poultry production, it cannot replace much of the concentrates.

368. Mature, weathered forage usually of low value.—In the semi-arid range districts, stock usually get most of their feed during the winter or during the dry season by grazing on forage which has matured and dried. As we have seen, mature grass is always low in protein and phosphorus and may have practically no carotene. If it is weathered by exposure to rains, the value will be lessened still further by leaching.

Where there is little or no rainfall after the grass matures, there is less loss through weathering, but still the mature grass will have a much lower value than before it matures. For this reason, cattle and sheep on range pasture make most of their gains in weight during the period when the forage is growing actively.

Weathered, mature forage resembles straw in composition and feeding value. It is very low in protein and phosphorus, it has practically no carotene, and it is lacking in palatability and is low in digestibility. When badly weathered, the forage may not even furnish enough nutrients for body maintenance. If stock receive no other feed, they may suffer severely from nutritive deficiencies. For example, it was found in California studies that because of the lack of carotene, cattle or sheep which had only such weathered range forage for long periods were often unable to produce normal offspring. (**192**)

Some forage plants lose much less nutrients by weathering than do others. For example, the wire grasses and sedges of the West often furnish much more nutritious winter feed than other grasses. Also, bur clover makes good feed even when mature, and winter fat (often called white sage) and some of the true sages have a good feeding value in winter. In general, the nutritive value of the grasses falls more with maturity and weathering than the value of the browse which stock get from the leaves and small twigs of shrubs.

369. Effect of grazing or frequent cutting on yield.—When grasses or legumes are cut at frequent intervals throughout the season, as on a well-kept lawn, the total yield of dry matter is usually much less than when they are allowed to grow to the usual hay stage.[14] This is because there is then a smaller leaf surface exposed to the sunlight. Therefore, the production of carbohydrates through the action of sunlight on the chlorophyll of the leaves is decreased. The same result is produced by close grazing of the crop.

The effect of frequent cutting or of close grazing will depend on the kind of plants and also on other factors. The yield of tall-growing plants, such as alfalfa, red clover, alsike clover, orchard grass, and the ordinary kinds of timothy, is reduced much more than that of low-growing spreading pasture plants, such as Kentucky bluegrass, Bermuda grass and white clover. Too-frequent cutting or too-close grazing of the taller plants may also seriously lessen their vigor, because of depletion of reserve food in the roots. This not only reduces the yield but may cause the plants to die out.

Differing from the yield of dry matter, the total yield of protein during the season may be greater when the crop is cut frequently or grazed than when it is cut for hay. Also, since very immature plants are lower in fiber and more digestible than at the hay stage, the yield of total digestible nutrients is not reduced so much as the dry matter.

In general, pasture mixtures of grasses and legumes which are cut every 2 to 3 weeks will yield only 50 to 70 per cent as much dry matter and 60 to 75 per cent as much total digestible nutrients during the season, as when they are harvested at the usual hay stages. In Pennsylvania tests pasture mixtures cut every month yielded only 66 per cent as much dry matter over a 5-year period as when 2 cuttings a season were made for hay.[15] Cutting the pasture mixture every week or continuous close grazing will reduce the yield even more.

Because continuous close grazing tends to reduce the yield of most pastures, the production of forage is usually increased somewhat when a system of rotation or alternate grazing is used instead. (376)

370. Effect of soil and fertilizers on composition.—Not only is the yield of a forage crop dependent on the amount of mineral nutrients in the soil, but also its composition may be greatly affected. Many experiments have been conducted to determine the effect of soil fertility and fertilizer applications on the composition of pasture, hay, and other forages.[16] Only a very brief summary of the more important findings can be presented here.

It is fortunate that the soil treatments which give the highest crop yields also generally produce forage of high nutritive value. Such forage will usually have a good content of protein and minerals, and it is apt to be richer in vitamins than forage that has made poor growth because of a lack of soil fertility.

Properly fertilized pasture plants continue growth over a longer period than those on infertile soil, and thus provide good feed for a longer time. Another important advantage is that pasturage on well-fertilized land is more palatable to stock than that grown on poor land. (98) This may largely be because the plants are more succulent.

Except where forage is deficient in phosphorus or in one of the trace minerals, the chief benefit from applying fertilizer to pastures or meadows is usually from an increase in yield, or from

an increase in the proportion of legumes. A larger proportion of legumes will, of course, decidedly increase the richness of the mixed forage in protein, calcium, and vitamins. Also, the nitrogen supplied by the legumes will tend to increase the protein content of the grasses in the mixture. (**449**)

Commonly, the yield of forage on phosphorus-deficient soil will be increased by phosphate fertilization much more than enough to repay the expense. In addition, liberal phosphorus fertilization will usually correct any phosphorus deficiency in the forage. However, a moderate application of phosphate to such a soil may at first only increase the yield, without increasing the percentage of phosphorus in the crop.

On phosphorus-deficient range pastures in the drier regions, the forage production per acre may be so low that it may not be at all practical to apply phosphate fertilizer to the soil. In such cases the phosphorus deficiency in the forage can readily be corrected by feeding bone meal or some other safe phosphorus supplement to the stock, as advised in Chapter VI. (**158–167**) Any deficiency of a trace mineral, such as cobalt, copper, or iron, can likewise be corrected by adding the trace mineral to the salt. (**172–173, 175**)

Where legumes do not thrive because of a lack of lime, phosphorus, or potash, adequate fertilization will commonly improve the nutritive value of pasturage and hay greatly. This is because it will increase the proportion of legumes in the forage.

Grass grown in partial shade, as in open woods, not only produces much less forage than that fully exposed to sunlight, but also is less palatable. This is probably because it has less sugars and starch.

371. Phosphorus and calcium content.—It has been emphasized in Chapter VI that grass or other forage grown on soil very deficient in phosphorus may be so low in this mineral that stock grazed on it suffer disastrously, unless fed a phosphorus supplement. (**150**) Pasture grass on phosphorus-deficient soil may contain less than 0.10 per cent phosphorus on the dry basis, in comparison with 0.20 to 0.40 per cent or more for grass from fertile pastures. In Texas studies it was concluded that pasture forage having less than 0.15 per cent phosphorus on the dry basis did not supply enough to meet safely the requirement of beef cattle grazed on the pasture without other feed.[17]

Legume forage is also much lower in phosphorus content than normal when grown on phosphorus-deficient soil, but the content does not usually drop to quite such a low level as in the case of the grasses. However, most legumes are exceedingly sensitive to a lack of this mineral nutrient and do not thrive or yield well unless there is an ample supply of phosphorus.

The percentage of calcium in non-legume forage crops is considerably reduced when the crops are grown on soil deficient in calcium. However, the calcium content is not often so low that livestock suffer from a lack of calcium. (**149**) While the percentage of calcium in legume forages depends to some extent on the calcium content of the soil, they are always relatively high in the mineral. When the soil is too deficient in calcium, the legume crop will not thrive, but the small amount of forage produced will be fairly high in calcium.

372. Protein content.—The yield of non-legume forage crops often depends largely on the amount of nitrogen in the soil. However, the percentage of protein in such crops is not affected by the supply of soil nitrogen to any such extent as a deficiency of soil phosphorus lowers the content of this mineral.

In the case of the grasses, the protein percentage at immature stages of growth is usually increased materially by nitrogenous fertilization, unless the soil is already well supplied with nitrogen. This increase may be sufficient to add appreciably to the feeding value of grass pasture or of grass hay cut very early. Also, nitrogen fertilization increases the palatability of the grasses.

The application of nitrogen fertilizer to grass early in the spring may not

increase the protein content appreciably at the usual hay stage, though increasing the yield considerably. By making a second application of nitrogen when timothy was heading out, the protein content of timothy hay was increased over 1 per cent in New Jersey tests.[18] By very heavy and repeated applications of nitrogen to Coastal Bermuda grass in experiments in southern Georgia, an average of 7.8 tons of hay per acre was secured, containing the high content of 12.7 per cent protein.[19]

Proper inoculation and also liming, when necessary, not only increase the yield of alfalfa and other legume forages, but in addition make them richer in protein. On the other hand, if such crops are well inoculated with the proper bacteria, nitrogenous fertilization will not produce much increase in the percentage of protein in the plants.

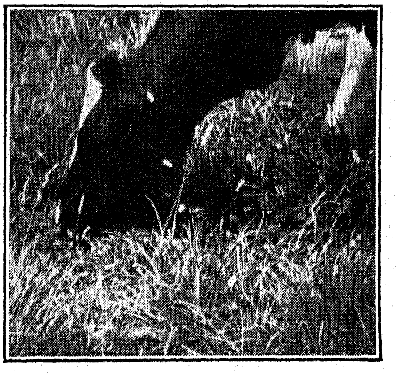
II. The Improvement and Utilization of Pasture

373. Importance of pasture improvement.—In spite of the great importance of pastures for livestock, pasture improvement received relatively scant attention in this country until recent years. All too commonly, farmers made little effort to increase the productivity of their pastures. They failed to treat pasture as a valuable crop. If the soil was fertile and the summer rains were timely, their stock thrived during the grazing season. On the other hand, if lack of fertility or drouth caused a serious shortage of feed in midsummer, the returns were much decreased.

Now, however, there is wide-spread interest in pasture improvement, and progressive farmers fully appreciate its importance. This change has come about largely through the numerous pasture experiments and demonstrations carried on by the state experiment stations and agricultural colleges, by the United States Department of Agriculture, especially through the Soil Conservation Service, and by other agencies. In addition, much excellent work on pasture improvement has been done abroad.

These studies show convincingly that in most localities a great increase can readily be made in the yield of pastures, and that wise expenditures for this purpose are usually highly profitable. In nearly all regions, pasture improvement will greatly reduce the cost of livestock production.

It is outside the scope of this volume to discuss in detail the fertilization and management of pastures under the various conditions throughout the country, or to review the results that have been secured in the numerous pasture investigations.[20] All that can be done is to summarize briefly certain of the most important findings. For further information the reader is referred to the publications of his state experiment station or agricultural college, or to those of the United States Department of Agriculture.



Cows Need Abundant Pasture

A cow has only a 3 to 4 inch "lawn mower" to harvest forage. Abundant pasture is needed, so she can get her fill without undue exertion. (From New York State College of Agriculture.)

Wherever a suitable legume will thrive in a pasture mixture, a much higher yield of forage is usually secured from a legume-grass mixture than from grasses alone. Such forage will have a considerably greater nutritive value, because of its higher content of protein, calcium, and vitamins. Also, a well-adapted legume-grass pasture will generally provide good feed over a much longer season than grass alone. Among

the legumes that are widely used in pasture mixtures in various parts of our country are alfalfa, Ladino clover, white clover, birdsfoot trefoil, and lespedeza.

The best mixtures to use for pasture on any particular farm is a local problem, the choice depending on climate, soil, and level of fertility. Therefore, anyone in doubt as to what mixture to use should consult his county agent or agricultural college, describing his local conditions. In a pasture mixture all the species of plants should be about equal in palatability. Otherwise the stock may not eat the less palatable plants.

Unless one is sure that the pasture will be well managed and tall growth will be clipped when necessary, it is a mistake to include in a mixture for a large pasture such a grass as orchard grass or tall fescue, which is low in palatability except when very young.

374. Proper grazing essential for high pasture yields.—Proper grazing management is essential for good results from any pasture. The chief objects are: (1) To keep the pasture plants growing actively over as long a period as possible, so they will provide palatable feed of high value; and (2) to encourage the growth of desirable grasses and legumes, while weeds, brush, and inferior grasses are crowded out. In general, the protein content of pasturage depends much more on proper management than on fertilization.

In all humid districts the pasture should be so managed that the grasses do not head out and go to seed. If the plants mature, the forage becomes unpalatable and of low nutritive value. Moreover, the new growth is diminished, and what there is may be wasted, because stock will refuse to eat the mature grass along with it. In addition, if the grasses grow so high as to shade a low-growing legume, such as white clover, they will drive it out. Weeds, brush, and coarse grasses are, moreover, apt to gain a foothold when the pasture is grazed insufficiently. A good rule is to graze the pasturage all down closely at least once a year.

Overgrazing throughout the season is one of the most common faults in pasture management. It not only reduces the yield, but it also weakens and drives out the most desirable pasture plants, because they are eaten down so closely that there is no opportunity for them to store reserve nutrients in their roots. Injury is especially apt to result if heavy grazing is begun before sufficient growth is made in the spring, and if the fall growth is grazed so closely that no cover is left for winter protection. In addition to these bad effects of overgrazing, it greatly increases soil erosion.

Such low-growing plants as Kentucky bluegrass and wild white clover will stand continuous close grazing much better than taller-growing plants. Alfalfa, Ladino clover, and bromegrass are all apt to be injured severely by constant close grazing and give the best results when grazed by the rotation method. (376)

In a pasture mixture of a tall grass with low-growing white clover or even Ladino clover, if the grass grows up too tall it will shade the clover and tend to kill it out. Such a pasture should therefore be grazed heavily during the flush of spring growth, so as to keep the grass down. If the forage gets ahead of the stock, the field should be cut for silage or hay.

In range areas stock commonly secure all or most of their feed in winter or in the dry season from standing mature grass and other forage that has been saved for this purpose. The nutritive value of such feed is apt to be so low that mineral or protein supplements are needed in addition.

Even in humid districts occasionally a field is not pastured the latter part of the season, but instead the forage is allowed to grow up and mature so as to supply feed late in the fall or in the winter. The advisability of such a practice will depend chiefly on the usual weather at that time of the year. At best, such forage is much less nutritious than immature forage or than good hay or silage.

375. Other points in pasture management.—Even when a pasture is well

managed, stock are apt to graze it unevenly. Some of the grass will head out and then may not be eaten during the rest of the season. If the land is not too rough or stony, it is wise to mow all such spots at least once a year at the usual haymaking time or before, to get rid of the old grass and to encourage new growth. It is especially important to cut all weeds and brush. If there is a uniform stand of good pasture plants in the pasture, with but few weeds, there may not be much advantage in mowing it when it is rather heavily grazed.

Stock will not graze the rank rings of grass around piles of droppings in the pasture, unless forced to it by hunger. Therefore in heavily-stocked cattle or horse pastures, there is considerable wastage of feed unless the droppings are spread at least once a year with a harrow.

A field will be grazed more uniformly if more than one kind of stock is pastured on it, and the return from the pasture may be thus increased.[21] Rotating two or more species of stock not only helps to control grazing, but it also aids in reducing the trouble from internal parasites.

For efficient use of the pasture, it is important to provide a good supply of water and also shade. Since stock on good pasture spend much of their time in the shade, if it is available, fertility is conserved when shade trees are located at the top of a slope, instead of at the bottom of the slope or on the banks of a stream.

The stock should be turned on a pasture in the spring just as soon as the plants have made sufficient growth and the soil is firm enough to stand trampling. If grazing is delayed longer, it may be impossible, during the period of rapid growth which follows, to prevent much of the grass from becoming too mature.

Grazing farm woodlots in the northern states is undesirable, for the stock secure but little feed and the reproduction of desirable trees is largely prevented. In a 5-year Wisconsin test, woods pasture produced only 276 lbs. of dry pasture forage per acre, in comparison with 1,453 lbs. for untreated open pasture and 3,210 lbs. for renovated pasture.[22]

North Carolina experiments indicate that careful grazing in the pine forests of the southeastern states may not do much damage to the forest growth, and it reduces the danger from damage by fire.[23]

Sometimes grass pastures are burned early in spring to remove dead vegetation or to kill undesirable shrubs.[24] While such burning may increase the spring growth of grass, annual burning is apt to be decidedly injurious over a term of years. This is because it destroys much organic matter and increases danger of erosion. Burning pastures is therefore advisable only under special circumstances and when recommended by agronomists familiar with local conditions.

376. Rotation or alternate grazing. —Especially for well-fertilized, high-yielding pastures, the method of rotation or alternate grazing is often used, instead of keeping the stock continuously on a single field throughout the season. Even on permanent pasture, rotation grazing tends to increase the yield of forage slightly. It is more advantageous with such pasture crops as alfalfa, Ladino clover, and bromegrass, which are injured by continuous close grazing. Such a combination as alfalfa or Ladino clover with bromegrass, timothy, or orchard grass, grazed rotationally or at least not overgrazed, will generally furnish much more good forage in midsummer than any permanent pasture.

In rotation grazing, there are 2 or more separate fields which are pastured in succession. After each area is grazed down, the animals are removed, and the forage is allowed to grow up to a height of 4 to 6 inches, before it is grazed again. Most of the feed is therefore eaten when it is rich in protein and digestible nutrients, and before it becomes less palatable. If the rainfall is abundant and the grass grows so fast the stock cannot graze it all, one of the areas should be cut early for silage or for hay, to prevent the bad effects of under-

grazing. The second growth of this area will then provide pasture during the midsummer season, when there is usually a shortage of good pasture.

Additional fencing is required for rotation grazing, and each plot must be accessible to a water supply. This can often be provided best by having the plots open into a common lane, where water is available.

Numerous experiments have been conducted in various parts of this country to compare rotation grazing with well-managed continuous grazing for dairy cows,[25] dairy heifers,[26] beef cattle,[27] and sheep.[28] These studies show that rotation grazing is very desirable for those pasture crops that do not stand continuous grazing well. Such pastures are alfalfa, Ladino clover, and mixtures of these legumes with a suitable grass. In most experiments rotation grazing of a permanent pasture has not increased the yield of forage enough to warrant much additional expense. In such trials the increase from rotation grazing has not exceeded 10 per cent, and in some experiments there has been little or no difference in yield.

High-producing dairy cows are benefited by rotation grazing more than are dairy heifers or beef cattle. This is because a high-yielding cow must have an abundance of feed throughout the season, or her milk flow will be seriously reduced. If her milk yield has once fallen badly, it is difficult to bring it back later by liberal feeding. On the other hand, while short pasture will reduce the gains of growing or fattening cattle, they will again make good gains later in the season if the forage becomes plentiful.

Rotation grazing is important for sheep, as it aids in preventing trouble from internal parasites. It is of similar advantage for horses or cattle in any area where infection with internal parasites is serious. In swine production fresh pasture, on which no swine have grazed that season, is exceedingly important for the young pigs at weaning time.

377. Strip grazing or rationed grazing.—Very recently there has been considerable interest in this country in "strip" or "rationed" grazing. In this method, which is often used in New Zealand for dairy cows, a fresh strip of pasturage is provided each day for the stock by means of electric fences. The width of each strip is adjusted so that it will furnish enough feed for the day. By this method there is less injury of the plants by trampling, but considerably more labor is required than in continuous or rotation grazing.

In a California experiment with dairy cows there was no appreciable difference in the results from strip grazing and from well-managed rotation grazing of irrigated Ladino clover-orchard grass pasture.[29] In a Minnesota test with heifers, the yield of forage was much greater with strip grazing than with continuous grazing, but the continuously grazed pasture was permitted to grow up without being clipped.[30]

In a California experiment with beef steers, 39 per cent more beef per acre was produced on alfalfa or alfalfa-grass pasture when strip grazed than when rotationally grazed.[31] The beef production per acre was still higher when the forage was cut and fed as green soilage. (387)

Comparisons over several seasons are needed to determine just how much increase in production can generally be expected from strip grazing, in comparison with well-managed rotation or continuous grazing.

378. Methods of pasture improvement.—The methods to be used in improving a run-down pasture should depend entirely on the conditions in that particular pasture. Proper grazing management is always necessary to get the best yield from pasture, but this alone will do little to improve a poor pasture.

If a run-down permanent pasture still has a fairly good distribution of desirable pasture plants, fertilization alone may be all that is needed to increase decidedly the yield of forage and to improve its nutritive value. Usually phosphorus fertilization is required on such a pasture, and lime or potash may also be needed. Adequate fertilization will greatly increase the stand and vigor of

desirable grasses and also on suitable soil will tend to bring back white clover or other adapted native legumes. Unless such fertilization will bring a considerable proportion of legumes into the pasture, nitrogen fertilization also will generally be needed.

Many experiments during recent years have shown that certain newer pasture combinations greatly surpass in yield and feeding value such permanent pastures as Kentucky bluegrass in the North or Bermuda grass in the South. Desirable combinations are alfalfa with bromegrass or timothy, Ladino clover with grass, and lespedeza and grass. More complex mixtures are often desirable, because the soil and drainage conditions may differ considerably in various parts of a field. Some of the plants in the mixture may thrive best in certain areas, while in other spots they may not do well, but will be replaced by plants that are suited to the conditions there.

If a run-down pasture is tillable, the best results are usually secured when the field is plowed, fertilized properly, and reseeded with an adapted high-yielding pasture mixture. Several experiments have proved that such pastures greatly excel well-fertilized permanent grass pastures. For example, in an Indiana test 2 acres of good bluegrass pasture were needed per dairy cow, while only 1 acre per cow of alfalfa-brome pasture provided a better supply of forage.[32] In addition, the growth of forage was sometimes so rapid the first part of the season that the excess was used for hay-crop silage. The superior nutritive value of the alfalfa-brome pasture is shown by the fact that the daily yield of milk per cow was 10 per cent higher than for the cows on the bluegrass pasture.

In Wisconsin tests the average yield of dry matter per acre over a 6-year period was 6,834 lbs. from alfalfa-brome pasture for dairy cattle.[33] Bluegrass pasture with complete fertilization, including nitrogen, yielded only 3,871 lbs. of dry matter a year over a 9-year period, and bluegrass without nitrogen fertilization but 2,361 lbs.

Similar improvement can be made in pasture for other classes of stock by plowing, fertilizing, and reseeding to a good pasture mixture. In the southern states the results are especially striking, because pasture can be provided during most of the year by a suitable combination of legumes and grasses. Thus, on light soil in Georgia the average yearly gain of beef steers on unimproved carpet grass pasture was only 76 lbs. per acre over a 10-year period.[34] On pasture which was reseeded to a mixture of Dallis grass, carpet grass, lespedeza, and white clover and which received a complete fertilizer, the average yearly gain per acre was 321 lbs. for the same period.

379. Renovating permanent pasture.—Old hillside pastures where there is danger of serious erosion if the land is plowed, and also pastures that are so stony or rough that plowing is difficult, can be successfully renovated without plowing. This is done by cutting up the sod thoroughly very early in the spring with a disk, spring tooth harrow, or cultivator, smoothing with a harrow, fertilizing adequately, reseeding with a suitable mixture of legumes and grass, and then covering the seed with a harrow or cultipacker. Stock must be kept off the renovated area until the new plants become well established.

In Wisconsin tests the annual yield of dry matter per acre on renovated pastures with moderate slope was double the yield on unrenovated pastures.[35] On steeper slopes the yield was increased still more.

380. Pasture fertilization.—Pasture fertilization is of two general types. The first is fertilization with phosphate or phosphate and lime, and with potash in addition, if needed. In this type of fertilization legumes are relied upon as the source of additional nitrogen. In the second type of fertilization nitrogen fertilizer is also applied.

The choice between the two methods should depend on the local conditions. Where a pasture mixture can readily be established and maintained which contains a considerable propor-

tion of a high-yielding legume, such as alfalfa or Ladino clover, there is no need of nitrogen fertilizer. Indeed, such a legume-grass combination will provide a much more uniform supply of feed throughout the summer than can be obtained from grass pasture, even with liberal fertilization. This is because these legumes make much more growth in midsummer than do most grasses, especially Kentucky bluegrass.

The forage from such a legume-grass pasture is also even richer in protein, minerals, and vitamins than the forage on a well-fertilized grass pasture. In addition, the cost of securing additional forage from pasture is much less when legumes are used to furnish nitrogen than when nitrogen fertilizer is used on a grass pasture, like Kentucky bluegrass.

This is shown in Wisconsin experiments in which bluegrass pasture with complete fertilization, including nitrogen, was compared with pasture in which a combination of alfalfa and grass was maintained by suitable renovation.[36] Both of these pastures were compared over a 7-year period with a bluegrass pasture which was fertilized with lime, phosphate, and potash, but with no nitrogen fertilizers. In comparison with this latter pasture, the alfalfa-grass mixture furnished additional digestible nutrients at only about one-half the cost of the additional forage secured by the use of the nitrogen fertilizer on bluegrass pasture.

By liberal use of a complete fertilizer, including nitrogen, on grass pasture, high yields of forage can be secured. Unfortunately, however, most of the additional growth from nitrogen fertilization comes in the spring and fall, when pasture is usually plentiful, and not during the period of midsummer shortage. This is because such grasses as Kentucky bluegrass make but little growth in hot, dry weather, even when liberally fertilized. On the other hand, plants such as alfalfa, bromegrass, or orchard grass, which are deeper-rooted and more drouth resistant, will continue to make considerable growth. Though Ladino clover is not very deep rooted, it makes much more growth in midsummer than bluegrass, unless drouth is severe.

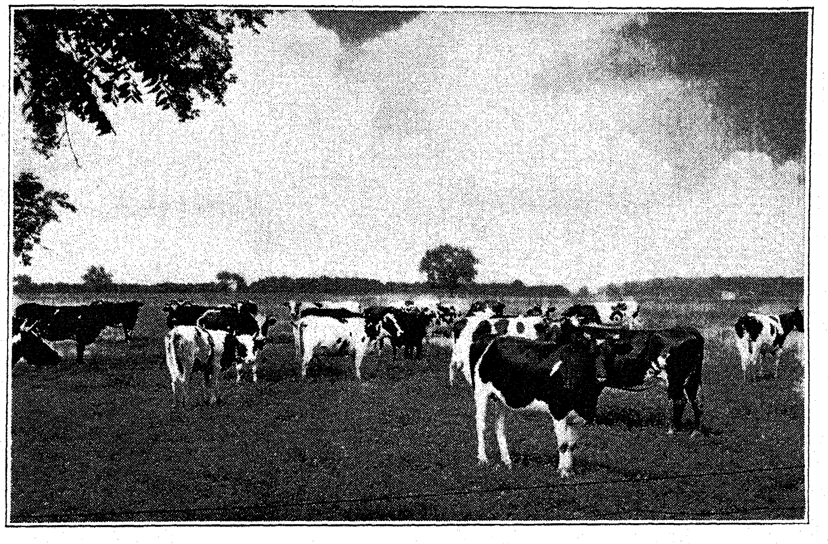
Nitrogen fertilization very early in the spring will stimulate the growth of grass so that the pasture will often be ready for grazing 10 days to 2 weeks earlier. By such fertilization of a suitable pasture field, the barn-feeding period for a dairy herd can generally be reduced appreciably.

381. Intensive pasture fertilization.—An intensive method of pasture fertilization, combined with rotation grazing, is sometimes used on dairy farms where the pasture area is very limited, as is often the case near large cities. Complete fertilizers are applied in liberal amounts, including a nitrogen fertilizer in early spring. Frequently nitrogen fertilizer is also used during the growing season to keep the forage growing rapidly over as long a period as is possible. The liberal fertilization with nitrogen stimulates the growth of grasses so much that they tend to crowd out legumes from the pasture.

In this system the pasture is divided into 4 to 8 paddocks, about equal in size, and often the herd is divided into 2 or more groups. The first group, consisting of the cows in milk, are pastured first for a few days on each plot in succession, thus getting the most liberal supply of forage. Then the dry cows and the heifers are turned into the plot to complete the grazing. Sometimes the cows in milk are divided into 2 groups, and the high producers grazed first on each plot.

In this system it is important to distribute the droppings by harrowing at least once a year. Also, a plot should be mowed whenever necessary to prevent the grass going to seed. Even under this system, it is difficult to provide ample forage on the pasture area itself during midsummer. Therefore, additional grazing should be furnished at that time, if necessary, by a field that has been cut early for hay, by Sudan grass pasture, or otherwise. This system is often called the Hohenheim system, from the Hohenheim Agricultural College in Germany, where it was first developed.

Experiments with this system in this country have shown that the yield of nutrients can often be increased 2 to 4 times over that on unfertilized pastures grazed by ordinary methods.[37] The cost of such a system of fertilization and management is considerable, but where the pasture area is limited, the method may yield good net returns, on account of the saving of other feed. It is doubtful whether even under these conditions it is as economical as the use of such legume-grass pasture mixtures as alfalfa-bromegrass or Ladino clover and grass, where such mixtures do well.



ABUNDANT MIDSUMMER PASTURE ON EARLY-CUT HAY FIELD

An excellent way to supplement short midsummer pasture is to use for pasture at this time the second crop on a mixed grass-and-legume hay field which has been cut early.

382. Providing good pasturage over a long season.—In order to secure the greatest net returns from livestock, it is essential that an abundant supply of good pasturage be provided over just as long a season as is possible. It has been pointed out in this chapter that such legume-grass combinations as alfalfa with bromegrass or Ladino clover with grass excel in providing high-quality forage over a long period. In particular, these combinations far surpass such permanent pasture as Kentucky bluegrass in furnishing feed in midsummer. However, even with these excellent combinations, there may often be a shortage of pasturage during a midsummer drouth.

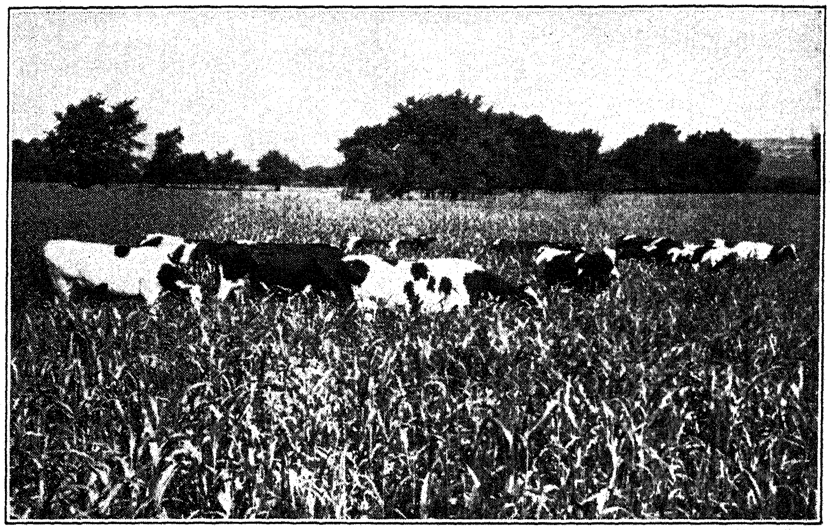
Especially for dairy cows, it is very important that additional roughage be supplied whenever there is a shortage on their regular pasture. An excellent way to supplement short midsummer pasture is to use for pasture at this time the second crop on a mixed grass-and-legume hay field that has been cut early.

Another method is to grow an annual crop like Sudan grass for pasture at this time. Sudan grass is especially adapted for midsummer pasture, for it stands drouth well and thrives in hot weather. If there is no drouth in midsummer and the Sudan grass is not needed for pasture, it can be made into hay or silage.

If pasture becomes short and no supplementary pasturage is available, then dairy cows should be fed silage, hay, or a green soiling crop to supplement what forage is available. This is generally much more economical than to keep up milk production by considerably increasing the amount of concentrates

fed the cows. It is shown later in this chapter that in this country silage generally furnishes cheaper feed than do soiling crops for supplementing short pasture. (386)

In the southern states it is important to utilize the mild winter climate fully by providing, over as long a period as possible, fall and winter pasture on legume-grass mixtures or on winter grain. Even in the more northern states the pasture season can be lengthened somewhat in spring and fall by pasturing winter grain. As has been mentioned previously in this chapter, early spring application of nitrogen fertilizer on grass pasture will often make it possible to turn stock on pasture 10 days to 2 weeks earlier.



SUDAN GRASS PROVIDES EXCELLENT MIDSUMMER PASTURE

Sudan grass furnishes excellent pasturage in midsummer when the forage on permanent pastures is apt to be scanty. (From New York State College of Agriculture, Cornell University.)

383. Nutritive value of fertilized and unfertilized forage.—Several experiments have been conducted to compare the production by livestock on fertilized and unfertilized pasture, and in other tests hay from a fertilized field has been compared with that from an unfertilized field. These experiments show clearly that when a soil deficiency causes the forage to be lacking in phosphorus or any other nutritive essential and the lack is not corrected by feeding a mineral or other supplement, proper fertilization to overcome the deficiency will be of great benefit.

For example, in recent California experiments in a phosphorus-deficient area of the Imperial Valley, steers fattened on alfalfa hay alone from unfertilized land made decidedly smaller gains and required more hay per 100 lbs. gain than did steers fed hay from phosphated land.[38] Similar results were secured in North Carolina trials with lambs fed soybean hay from phosphated and unphosphated land.[39] In an area of Oregon where the soil is extremely low in sulfur, sulfur fertilization not only greatly increased the yield of alfalfa, which has a high requirement for this mineral, but it also considerably improved the value of alfalfa hay for fattening lambs.[40]

Even when a suitable mineral supplement is supplied the animals, the forage from a well-fertilized pasture will usually produce much better results than that from an infertile field. This is chiefly because the rate of growth will be more

rapid and more continuous. There will therefore be a better supply of feed throughout the season. The fertilized forage will also be more palatable, and the animals will hence eat a greater amount per day. Another advantage is that the proportion of legumes in a pasture mixture is usually increased by suitable fertilization. This decidedly increases the value of the forage, as has been pointed out previously.

The extent of the difference between the production of stock on unfertilized pasture or hay and on pasture or hay from fertilized land will depend primarily on whether or not any nutritive deficiency results from feeding the unfertilized forage. For example, when the concentrate mixture fed dairy cows supplies plenty of phosphorus, a higher phosphorus content in hay produced by phosphorus fertilization may not make the hay more valuable per ton. However, the fertilization may be decidedly profitable because of the increased yield secured.

Though the forage from unfertilized land may be very scanty in amount, the nutritive value per pound may be as great as that of the abundant forage from a well fertilized field. This is shown by experiments with dairy cows at the Michigan, Nevada, and Virginia Stations.[41]

The most extensive of these experiments was that by the Michigan Station. In this investigation part of a rundown farm was limed and heavily fertilized with a complete fertilizer, including trace minerals. The other part received no lime and no fertilizer, except that some nitrogen fertilizer was necessary to grow enough feed for the cows. One group of cows was fed entirely on feed from the unfertilized area, and another group on that from the well fertilized land.

No legume forage was grown on either part, because alfalfa or clover would not grow on the unfertilized runout soil. The cows in each group were fed a balanced ration made up of timothy and bromegrass hay and a concentrate mixture of ground grain and soybeans, all raised on the respective area. Of course, a far larger acreage of land was needed on the unfertilized part of the farm to produce the feed for each cow.

The results were surprising. During 5 years no difference in the feeding value of the two rations could be detected. The cows fed the ration from the unfertilized land were just as healthy and produced as much milk as the others, and there was no difference in the nutritive value of the milk.

384. Supplemental irrigation of pastures.—With the development of readily movable irrigation systems, consisting of sprinklers and light-weight aluminum pipe, some farmers in the humid regions of the United States are now using supplemental irrigation to keep pastures growing during drouths. This is usually done on improved, well fertilized pastures seeded to a mixture that has high productive capacity.

The increase in yield obtained by such irrigation depends, of course, on the amount and distribution of rainfall in the particular season. In several tests by experiment stations, supplemental irrigation in humid regions has usually increased the yield of pasturage by 30 to 40 per cent or more, except when the rainfall during the season was plentiful and well distributed.[42] The economy of this method of increasing pasture yield depends largely on the cost of securing a supply of water that will be adequate when needed.

In the western irrigated districts high yields of pasture forage are obtained on fertile soil with proper management. For example, in western Montana the average carrying capacity on a good irrigated pasture mixture over a 10-year period was 2.2 dairy cows per acre during the season.[43]

385. Range management and improvement.—While it is generally best in humid districts to graze pastures sufficiently close so that the grasses do not go to seed, the conditions are entirely different on the western ranges. On account of the limited rainfall, care must be taken there not to overgraze the land. Otherwise, the desirable forage plants

will be killed and only those left which are relatively unpalatable and of low value. Also, the land will then be subject to much more injury by erosion.

To produce the most feed, the grasses must have a chance to form seed at least every 3 or 4 years, and the following spring the young seedlings should be given a chance to grow. No range should be grazed in the spring until the grass has made sufficient growth and the soil is reasonably dry. Poisoning of stock often results from forcing the animals to graze the scanty growth too early, for some of the poisonous plants start growth earlier than the grasses or other good forage and are therefore eaten, when they would otherwise be left untouched.

The range should not be grazed so heavily that the forage is injured badly by trampling or unduly close cropping. Otherwise, not only will the grasses and other herbaceous plants be destroyed, but also the shrubby browse will be injured, which forms a large part of the feed on some of the mountain ranges. Watering places should be developed close enough together to avoid overgrazing near the water supplies. Salting the stock at well-selected places will aid in relieving areas that are being injured by too close grazing. In normal years, when the stock come off a range, it should be in good condition and with some feed left.

Through improper management and unrestricted grazing, the carrying capacity of many western ranges was seriously reduced. During recent years much valuable information has been secured about the best methods of range restoration and improvement and of reseeding abandoned crop land in experiments by the state experiment stations and the United States Department of Agriculture.[44]

Where a range has been so badly injured that few desirable plants are left, reseeding may be advisable, if the rainfall is usually sufficient to secure success. More commonly, grazing on part of the area is deferred until after the grasses have matured seed. The following year, another area is similarly treated. This method of deferred and rotation grazing usually increases the carrying capacity of the range considerably, unless the pasturage is already better than the average. In some experiments the carrying capacity of range land has been considerably increased by a method of increasing the absorption of rain and reducing run-off, such as pitting, chiseling, or furrowing the land. On some ranges, it may be possible to spread the water at times of high water in a stream, by means of small dams.

The great improvement that results from controlled grazing and proper management has been well demonstrated in the National Forests, where the grazing is under very definite regulations.

III. Soiling Crops

386. Soiling crops.—*Soiling crops* are green forage crops that are cut and fed in fresh condition to stock. Soiling crops are often called "soilage." Years ago the growing of a succession of soiling crops was sometimes advocated in this country to furnish green feed throughout the growing season, especially for dairy cows.

It has been pointed out previously in this chapter that a considerably larger yield of nutrients is generally secured when a crop is allowed to grow to the hay stage than when it is kept grazed during the season. For this reason, and also because none of the forage is wasted by the trampling of stock, an acre of land will usually furnish much more feed when used for soiling crops than for pasture. In addition, less fencing is needed than when the feed is furnished by pasture.

These advantages of soiling crops were, however, more than offset by the high cost of growing special soiling crops and harvesting the forage each day by the means then available. Therefore this method was used here but little.

Experiments by the Iowa, Nebraska, and Wisconsin Stations showed definitely that the production of dairy cows was maintained just as well on silage plus limited pasture and a suitable supply of

concentrates, as when soiling crops were fed in place of the silage.[45] Also, the cows liked corn or sorghum silage as well or even better than a succession of different soiling crops.

In the Iowa trials it required 180 lbs. of soiling crops to equal 100 lbs. of corn silage in feeding value, because the soiling crops contained much smaller percentages of dry matter and digestible nutrients. In the Nebraska trials a much larger area was needed per cow to provide the feed when soiling crops were used, than when corn silage and alfalfa hay were fed.

Because of the expense involved in using special soiling crops, they have not commonly been grown in the United States for feeding during the entire season. They have been used more often to supplement permanent pastures during a midsummer drouth or at any other time when the pastures provide insufficient feed. Even for this purpose, it has usually been much cheaper to grow such crops as Sudan grass to be used for temporary pasture, or to pasture the second crop on a hay field, or to feed silage or hay as the supplement to scanty pasture.

In case the pasture becomes parched and none of these other provisions has been made, it is certainly wise to cut and feed green some crop that has been raised in the regular rotation and which is ready for use at that time. Excellent crops for this purpose are green alfalfa, clover, the hay grasses, or corn.

In countries where labor is relatively cheap in comparison with the price of land, a much wider use is made of soiling crops than in this country. Soiling crops are used extensively, especially for dairy cows, in certain tropical and semitropical regions where large yields of green feed can be provided the year around by such a soiling crop as Napier grass.

By the use of a field chopper, or forage harvester, the time required for the daily harvesting of a soiling crop is much less than with the older methods, if a considerable number of animals are fed. Therefore, there is now renewed interest in the use of soiling crops, or "zero pasture," as it is sometimes called, for utilizing high-yielding forage crops. By successive cuttings, properly arranged, of such crops as alfalfa or a mixture of legumes and grasses, good feed can generally be provided throughout the season. Thus the expense and trouble of planting a special succession of crops for soilage is avoided.

387. Soiling crops vs. pasture.—Sufficient data are not yet available to show conclusively the relative economy under average conditions in this country of such use of soiling crops for dairy cattle or other stock, in comparison with well-managed pasturing, or with limited pasturage supplemented with silage or hay. To draw definite conclusions, complete data would be needed, including not only the production of milk or meat per acre with the different methods, but also accurate records of the labor cost and other expenses.

In a recent New Jersey trial with dairy cows, the milk production was maintained better on soiling crops than on pasture, but it required 3.1 hours a day to cut and haul the green feed for 50 cows.[46] In a Rhode Island experiment the milk production of cows fed soilage was appreciably higher than of others on pasture, and 22 per cent more milk was produced per acre.[47] In contrast with these results, in a Minnesota trial the milk production was no higher from cows fed alfalfa-bromegrass soilage than from cows grazed rotationally, but less area was needed per cow when soilage was fed.[48]

The gain of beef steers per acre of alfalfa was 69 per cent more in a California trial when the crop was fed as soilage than when the cattle were grazed rotationally.[49] The results were better when the alfalfa was fed fresh than when it was fed after wilting. In a Colorado test there was no significant difference in the gains of full-fed fattening cattle fed fresh-cut alfalfa, and of those fed alfalfa hay or grazing irrigated alfalfa.[50]

In pasturing a tall-growing crop, such as Sudan grass, there is a greater wastage of feed from trampling than on

an ordinary pasture, and consequently more advantage in feeding it as soilage. In a North Dakota trial the value of Sudan grass for sheep was about twice as great per acre when it was fed as soilage as when it was grazed.[51]

QUESTIONS

1. Why is pasturage usually the most economical feed for cattle, sheep, and horses during the growing season?
2. Discuss the influence of stage of maturity of forage crops on content of nutrients, considering the following: (a) Protein; (b) digestible nutrients; (c) phosphorus and calcium; (d) vitamins.
3. What is the effect of rate of growth and season of year on the composition of grass?
4. Give examples of marked differences between various pasture and hay plants in regard to the effect of advancing maturity on composition.
5. State 3 forage crops which are richest in nutrients when mature, and tell why this is so.
6. Why will immature forage, such as pasture grass, not fully take the place of concentrates in livestock feeding?
7. Discuss the composition of mature, weathered grass, and the effects upon stock receiving only such feed.
8. What is the effect of frequent cutting or continuous close grazing upon the total yield of dry matter by pasture or hay crops?
9. Discuss the influence of soil fertility on the composition of forage crops, considering content of protein, phosphorus, calcium, and vitamins.
10. Discuss the importance of pasture improvement.
11. State the essentials of proper grazing management to secure high pasture yields.
12. What are the advantages and disadvantages of rotation grazing for various kinds of stock?
13. What is strip grazing? Is this method used in your locality?
14. How should a run-down pasture be improved?
15. Explain the two general types of pasture fertilization. How would you decide which system to use on a particular farm?
16. Describe the intensive system of pasture fertilization and management, known as the Hohenheim system.
17. What methods can be used to provide good pasturage over a long season?
18. Discuss the nutritive value of fertilized and unfertilized forage.
19. How much has supplemental irrigation increased pasture yields in humid regions?
20. In what respects does the improvement of a range in the West differ from the improvement of pastures in a humid district?
21. What are soiling crops? Why is there now greater interest in the use of soiling crops than several years ago?

CHAPTER XIV

HAY AND HAYMAKING

I. Principles of Haymaking

388. Importance of efficiency in haymaking.—Throughout the temperate regions of the world hay is the most important harvested roughage for livestock. Very heavy losses of feeding value occur each year in this major crop, because hay is cured or stored improperly. Indeed, the losses in the hay crop are far greater than those in any other agricultural crop.

In addition to the waste of feeding value in poor hay, there is a huge loss each year through farm fires caused by spontaneous combustion. This waste, which is estimated at $30,000,000 or more a year in the United States, is due chiefly to the storage of hay when it contains an unsafe amount of water.

Most of these heavy losses can be prevented by efficient methods of haymaking, combined with good judgment. It is therefore important that every stockman understand clearly the principles which make possible high efficiency in haymaking.

The importance of the hay crop in the United States is shown by the fact that over 100,000,000 tons of hay are made a year from an average of about 73,800,000 acres. This annual hay crop has a farm value of nearly two billion dollars.

389. Characteristics of high-quality hay.—Since it is the object in haymaking to produce hay that has a high feeding value, let us first consider the characteristics of such hay. To be of high quality, hay must have been made from plants cut at a sufficiently early stage of maturity. Next, high-quality hay has been cured and handled so that it is leafy and green in color. The stems are soft and pliable. It is free from mustiness or mold. It is palatable, because of its fragrance and also because of its content of sugars and other soluble nutrients. It has but little foreign material, such as weeds or stubble.

Such hay is more nutritious and more palatable than that which does not possess these qualities, and it therefore has a much higher feeding value per ton. Indeed, there may be far more difference in actual value per ton between good and poor hay of any particular kind than there is between the different kinds of hay made from the various common hay crops. Most kinds of hay of the same grade or quality generally supply about the same amounts of total digestible nutrients, regardless of kind or variety. However, legume hay, such as alfalfa or clover, is of course much richer in protein, calcium, and vitamins than is grass hay of equal quality.

The Federal hay grades, by which hay is sold on the larger markets in the United States, are based on the qualities which good hay should have.[1] Any person who produces hay for such markets should familiarize himself with these grades, for the price paid for any lot of hay depends strictly on the quality as indicated by the Federal grade.

390. Usual grades of hay on farms.—To secure information on the grades of hay actually produced on northeastern farms, a 3-year study was made by the New Jersey Station and a 2-year study by the New York Station.[2] In these studies 2,567 samples of hay, mostly first cutting, were secured from farmers' barns during the winter feeding season and graded according to the official United States hay grades. On the average, 20 per cent of the lots of hay graded No. 1 (excellent hay), 45 per cent No. 2 (fairly good hay), 19 per cent No. 3 (rather poor hay), and 16 per cent Sample Grade, because of mustiness or mold, or being over-ripe or high in foreign mat-

ter. In the New York studies the average grade of the first cutting hay was 2.2, and of second-cutting hay, 1.8.

Probably the average grade of the hay fed on all the farms in the region would have been slightly lower than on the farms studied, because the least progressive farmers are less apt to cooperate in such investigations.

These and other studies show the need of improvement in haymaking, in order to secure the maximum feeding value from this important crop. The studies show that the chief factors in producing high-quality hay are cutting at the right stage of maturity, proper curing to retain leafiness and green color, control of foreign material, and storing only when the moisture has been reduced to a safe level.

391. Value of good and poor hay.—The great difference in feeding value between good hay and poor hay is well shown in recent experiments by the United States Department of Agriculture with dairy heifers.[3] During two winters one group of heifers was wintered on good alfalfa hay, U.S. No. 1 or 2, containing 23 to 27 per cent fiber. Another group was fed poor alfalfa hay, U.S. No. 3, having 33 to 34 per cent fiber. The heifers fed the good hay gained 28 per cent more and required 12 per cent less hay per 100 lbs. gain than those fed the poor hay.

Good and poor hay were also compared in a trial by the Ohio Station with steers full-fed corn-and-cob meal plus 1.5 lbs. of soybean oil meal per head daily.[4] Though these cattle, liberally fed on concentrates, did not eat an average of more than 2 lbs. of hay a day, nevertheless the quality of the hay made a difference of 0.3 lb. in the average daily gain. The difference in actual feeding value between the good and the poor hay was far greater than the $7.50 per ton difference in cost.

392. Importance of early cutting.—It has been shown in the previous chapter that the percentage of protein, the digestibility, and the content of minerals and vitamins all decrease decidedly as hay crops advance in stage of growth. (**358–362**) The rate of decrease in nutritive value tends to be more rapid in most grasses than in legume hay crops, such as alfalfa or clover.

Because of these changes in composition, hay that is cut late has considerably lower feeding value than that which is cut early, if the early-cut hay is cured equally well. Other factors than the nutritive value of the hay per ton must, however, be considered in deciding when to cut various crops for hay.

In humid regions it is usually much more difficult to cure the first cutting of hay satisfactorily, if it is cut extremely early. This is because of several factors. The plants then have a much higher percentage of water. They are also more hygroscopic,[5] and harder to dry, because of a greater content of sugars and other soluble nutrients. The soil is generally more moist early in the season, and the weather less suitable for rapid curing. There is more apt to be damage from rain.

Although early cutting considerably increases the feeding value of hay per ton, if it can be cured well, very early cutting may decidedly reduce the annual yield of dry matter. The smaller yield of a very early first cutting will usually be made up partly by a greater growth of aftermath, but the total yield of dry matter is frequently less. On the other hand, a higher yield of protein per acre is often secured by very early cutting.

An important fact is that repeated very early cutting of a tall-growing hay crop, especially alfalfa, is apt to reduce the stand seriously, because the plants die out due to depletion of nutrients in the roots. (**454**) Information is given in Chapters XVI and XVIII on the best stage for cutting various hay crops.

Experiments have shown that it is not necessary to cut a crop at an impractically early stage to secure hay of high feeding value. The chief decline in nutrients comes after the crop reaches full bloom, and especially when seed has developed. When one has a large acreage of hay, it is necessary to start haying

early enough to finish it before the last of the crop gets too mature.

The actual difference in feeding value per ton between hay cut in early bloom or before and that cut when the crop is in full bloom will depend on the class of stock to which it is to be fed. The difference is greatest where the hay is used as a vitamin supplement for swine or poultry. For this purpose, hay that is early-cut, leafy, and well-cured is essential, as the vitamin content is otherwise much lower. Early-cut hay should also always be used, if possible, for dairy calves and sheep. In storing the hay crop, some of the best hay should therefore be put where it will be accessible for these uses.

The difference in value between early-cut hay and that cut in full bloom is less for dairy cows and beef cattle, especially when silage is fed in addition to the hay, or when concentrates are fed liberally. For work horses or light horses hay cut when in bloom is preferred to that cut earlier, because hay cut extremely early is apt to be too laxative. Hay cut very late—in the seed stage or later—has a low value for all classes of stock.

When dairy cows were fed concentrates at a rather low rate with timothy hay as the only roughage, the milk production in New York trials on hay cut in the seed stage was only 59 per cent as much as on hay harvested when the timothy was heading out.[6] Also, the cows fed the late-cut hay lost 1.5 lbs. per head daily in weight, while those fed the early-cut hay gained 0.6 lb. a day. In another trial in which concentrates were fed liberally, 90 per cent as much milk was produced on the late-cut hay as on that cut early, but there was a difference of 1.1 lbs. a day in the gain in weight per cow.

Dairy heifers gained in weight and stored protein in their bodies in New Hampshire experiments when fed only timothy hay cut before bloom, but lost weight and protein on timothy hay cut in the seed stage.[7] Similarly, in Nebraska trials beef calves wintered on early-cut prairie hay made fair gains, but others fed prairie hay cut in September lost weight.[8] To produce as good results on the late-cut hay as on that cut early, it was necessary to feed one-half pound per head daily of protein supplement.

393. Reduction in water content.—The primary object in haymaking is to dry the green plants enough so that the hay can be safely stored without heating unduly or becoming moldy. For hay to keep safely in barn or stack, the water content must be reduced to not more than 25 per cent. If the hay is chopped or baled at time of storage the percentage of water should not be over about 22 per cent. Hay containing too much moisture when stored will undergo pronounced fermentation and become very hot. The value may be greatly decreased because of mold or the losses of nutrients which occur in the extensive fermentations. Also, there is always danger of spontaneous combustion when hay is stored with too much moisture. The slight fermentation, or sweating, that occurs in properly-cured hay when it is stored does not cause any marked loss of green color or nutrients. It even seems to improve the aroma and palatability of the hay.

Some believe that it is safer to store hay with a high moisture content when this is due to the moisture content of the plants, than when the hay has been dampened by rain or dew. It is not wise to rely on this. The only safe way to avoid serious loss is not to store any hay when it is too high in moisture, no matter what the cause.

A practical method used by farmers to find out when hay is cured sufficiently for storage is to twist a wisp of it in the hands. If the stems are slightly brittle and there is no evidence of moisture when the stems are twisted, the hay can be stored safely. In excellent curing weather the hay may appear drier than it really is, especially if cured chiefly in the swath. This is because the leaves will be dry and brittle, while the stems are still too high in moisture.

Among the various rapid methods devised for determining whether hay is dry enough for storage, one of the sim-

plest is the following, suggested by Dexter of the Michigan Station.[9]

A large representative handful is carefully selected and then bent or twisted to break the stems somewhat. From the center of the sample a portion is cut, approximately as long as a quart glass jar and sufficient to fill it loosely. The sample is placed in the jar, a teaspoonful of fine-grained table salt is added, and the cover placed on the jar. The sample should not fit so snugly as to prevent free circulation of the salt.

The jar is shaken about 100 times to keep the salt and hay moving about. Then the jar is held upside down and the salt is shaken into the cover, where it can be examined. If the hay is dry enough for safe storage, the salt will still be in small grains. On the other hand, if the hay has more than about 25 per cent water, the salt will have taken up moisture and be gathered in clumps. Samples that are distinctly too wet will change the salt in about 30 seconds. In border-line cases, the sample should be shaken again and allowed to stand for a few minutes.

The method may also be used for oats, barley, or wheat grain. Ten or more representative heads are threshed out, placed in a small container with about one-half teaspoonful of salt, and shaken about 50 times. The salt will stay dry if the grain has less than about 14 per cent water.

If it seems wise, because rain is threatening, to haul hay to the barn before it has reached the desired dryness, it should be spread out well in a mow to a depth not greater than about 3 to 5 feet. Special care should be taken not to leave any large, compact masses where the hay falls from the hay fork or sling. If possible, such hay should not be covered with other hay until it has cured out somewhat. The barn doors should be left open for ventilation.

394. Losses of nutrients in haymaking.—Some nutrients are always lost in the field-curing of hay, but under favorable conditions this loss is not large. However, the wastage may be great unless proper care is taken. These losses are not due to the mere drying out of the forage plants. Experiments have shown definitely that the drying of green grass or other green forage at ordinary temperatures does not reduce is digestibility.[10] Also, when plants are dried without any bleaching or fermentation, they have a high content of the vitamins that are of importance in stock feeding.

The losses that occur in haymaking are: (1) Losses of leaves and other finer parts by shattering; (2) losses by fermentation and bleaching; and (3) losses of soluble nutrients by leaching, in case of heavy rains.

395. Losses by shattering.—The leaves of legume hay dry out much sooner than the stems, and if they become dry and brittle they shatter badly when the hay is raked or otherwise handled. This loss of leaves is serious, for the leaves have 2 to 3 times as much protein as do the stems. They also contain most of the carotene and other vitamins, are much richer in minerals, and have much less fiber. The proportion of leaves is hence one of the most important factors in determining the feeding value of any particular lot of hay.

Legume hay, especially alfalfa, should therefore be raked before the leaves become dry. If the hay has dried out unduly before it is raked, it should, if possible, be raked early in the morning when it is damp with dew.

That the loss of leaves from alfalfa hay is large, even with modern haymaking methods, is shown by recent United States Department of Agriculture experiments.[11] An average of 38.5 per cent of the leaves of alfalfa was lost from field-cured hay in good weather with no rain, and as much as 74.5 per cent when the hay was wet by 3 showers. In very dry climates the loss by shattering may be even larger, unless great care is taken.

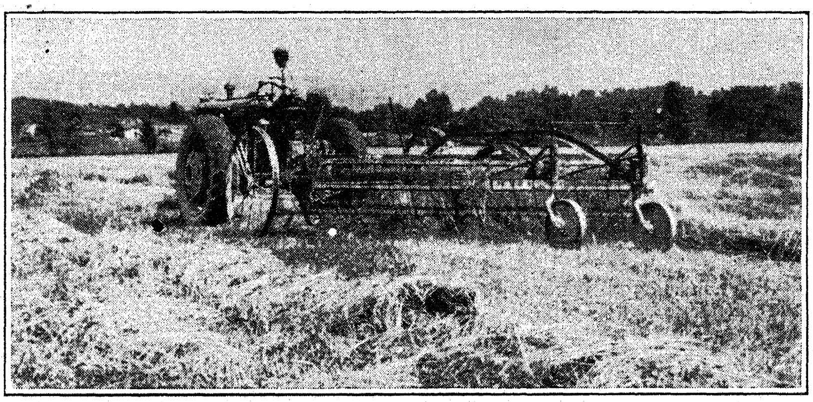
396. Losses by fermentations and bleaching.—Even in excellent haymaking weather, the curing of hay in the field is not merely a simple process of drying. Fermentations take place in which some of the organic nutrients, especially the sugars and starch, are oxidized to carbon dioxide and water, thus being lost. Also, fermentation has a very destructive effect on the carotene in hay. If the weather is favorable and the hay is cured by proper methods, without undergoing pronounced heating, the losses by fermentation will be relatively small.

However, rainy weather, which greatly prolongs the curing process, increases the losses. If very extensive fermentations take place, as in brown hay, a heavy loss of carbohydrates will occur and also the carotene and other vitamins will be largely destroyed. (412)

If hay is badly bleached by long exposure to the sun, nearly all the carotene will be lost. In general, the amount of carotene in hay is proportional to the greenness in color. Green-colored hay is nearly always rich in carotene and straw-colored or brown hay very poor in it.

However, unless the rain is so heavy that the hay is thoroughly soaked and washed by the rain, there will not be much loss by leaching. Also, severe leaching results only when the hay has dried out considerably before the rain comes. Hard rain soon after the crop is cut does not cause much loss.

398. Extent of total losses in hay.—The total loss of nutrients in hay during field curing and subsequent storage in the mow before feeding will vary widely. In fairly good haymaking weather and with proper methods, the



LOSSES OF NUTRIENTS REDUCED BY GOOD HAYMAKING METHODS

To produce high-quality hay, leafy and green in color, hay should be raked into small, loose windrows, after it has partly cured in the swath. (From New York State College of Agriculture, Cornell University.)

The losses by fermentation do not cease when hay is stored in the barn. If the hay is well dried and does not heat unduly in the mow, the loss of dry matter in barn storage for 6 months will usually not exceed 5 to 7 per cent. When hay is under-cured and molding or severe heating occurs, the loss is much greater. As has been shown in Chapter VII, a continual loss of carotene takes place in hay during storage. (195)

397. Loss by leaching.—If hay that is already nearly cured is exposed to heavy and prolonged rain, especially when it is in the swath, severe losses may occur through leaching.[12] At least 20 per cent of the protein and considerably more of the nitrogen-free extract may thus be lost by leaching.

total loss of dry matter from the green crop to the manger should not exceed 20 to 30 per cent for legume hay and 10 to 15 per cent for grass hay. Under unfavorable conditions the loss will be considerably higher.

Extensive experiments have been conducted by the United States Department of Agriculture and at Cornell University and the University of Vermont to study the losses of dry matter and nutrients in various methods of handling hay crops.[13] Similar studies have also been made at other institutions.[14] In the United States Department of Agriculture investigations with 7 harvests of first-cutting alfalfa, the total loss of dry matter in field-cured hay, from the time it was cut in the field until it was fed in winter,

averaged 21.0 per cent when the hay was not rained on and 36.6 per cent when there were rains during curing. Most of this loss occurred before the hay was stored, the loss of dry matter during storage being not over 4 per cent.

The total loss of dry matter in barn-dried hay, from cutting to feeding, averaged 19.0 per cent when the air was not heated and only 15.2 per cent with heated air.

The total loss of dry matter was least for dehydrated hay, the loss from cutting to feeding being only 9.7 per cent. Wilted silage ranked low in total loss of dry matter, the average being 16.8 per cent, of which 11.0 per cent occurred in the silo.

The losses of protein and of total digestible nutrients were somewhat greater than for dry matter. On the average, 27.7 per cent of the protein and 25.5 per cent of the total digestible nutrients were lost in field-cured hay in good weather; 24.0 per cent of both protein and total digestible nutrients in barn-cured hay without heated air; 18.2 per cent of the protein and 13.1 per cent of the total digestible nutrients in dehydrated hay; and 16.9 per cent of the protein and 19.5 per cent of the total digestible nutrients in wilted silage.

The losses of carotene were very heavy in all methods. Even in dehydrated hay 76 per cent of the carotene was lost from cutting to feeding. The loss for wilted silage was 81 per cent; for barn-dried hay (no heat), 94 per cent; for barn-dried hay (heated air), 90 per cent; and for field-cured hay (good weather), 97 per cent. In spite of these very great losses, the original carotene content of the green alfalfa was so high that even the field-cured hay made in good weather had plenty of carotene, when fed, to meet the vitamin A needs of dairy cows. On the other hand, the field-cured hay that was rained on was deficient in carotene.

The carotene content per pound of dry matter of the alfalfa when fed was: wilted silage, 28.1 mg. (milligrams); dehydrated hay, 26.0 mg.; barn-dried hay (heated air), 14.2 mg.; barn-dried hay (air not heated), 9.3 mg.; field-cured hay (good weather), 5.4 mg.; and field-cured hay (rained on), only 1.7 mg.

II. Haymaking Methods

399. Modern methods of curing hay.—Several experiment stations have conducted investigations to find the most economical methods of making good hay, especially legume hay.[15] The most important results of these experiments are summarized in the following articles. These studies have shown that proper equipment not only greatly decreases the labor cost, but also is important in improving the quality of the hay.

The experiments have shown that hay dries much more rapidly in the swath than in the windrow, even if the windrow is small and loose. However, claims are often made to the contrary. The larger the windrow is, the slower will be the curing, and the rate is still slower in cocks.

Though hay cures rapidly in the swath, it is not advisable to cure it entirely there, except perhaps with grass hay in cool, dry weather. When curing is completed in the swath, the leaves become dry and brittle long before the stems have dried out sufficiently. With legume hay, especially alfalfa, a heavy loss by shattering of the leaves will then take place when the hay is handled. Also, the prolonged exposure to the sunlight will bleach the hay and destroy much of the carotene.

On the other hand, if the green forage is raked into a windrow, even a small, loose one, immediately after it is mowed, an unduly long time will be needed for curing, except in a very dry climate. Fermentation and molding may occur, which will seriously damage the hay. Such slow curing also increases the risk of damage from rain.

For the production of high-quality hay, leafy and green in color, with a minimum of labor, the following method is generally best: First, even if there is a dew in the morning, experiments have shown that there is no advantage in delaying mowing until the dew has dried off. In most cases, hay mowed early in

the morning will be drier by afternoon than that which has been cut later in the day. No more hay should be mowed at a time than can be taken care of properly under usual weather conditions.

After mowing, let the crop lie in the swath for a few hours, until it is partly cured. Before there is danger of the leaves shattering, rake it into small, loose windrows, preferably with a side-delivery rake. As long as the leaves remain alive, they may perhaps help to dry out the stems, by pulling water from them as the leaves evaporate it.[16]

mower, to crush the stems and hasten the drying. After the crushing, the hay is dropped to the ground and cured in the usual manner. Tests have shown that the curing time is usually reduced decidedly by crushing.[17] However, the high cost of the equipment is a deterrent to its use, except on farms where there is a large acreage of hay.

400. Curing hay in cocks.—Before the modern, labor-saving methods of making hay were developed, it was generally advised that to make hay of the best quality, regardless of expense, it

CURING HAY IN COCKS REQUIRES MUCH LABOR

The color and carotene content are well preserved when hay is put in well-made cocks as soon as it has dried enough so that it will not mold. However, this method requires too much labor for use on any large acreage.

should be put in well-made cocks as soon as it had dried enough so it would not heat or mold. This method preserves the color and carotene content, but it requires too much labor for use when there is any considerable acreage. Also, in a humid climate there is much risk of damage from rain before the cocks dry out, unless one goes to the further considerable expense of covering the cocks with hay caps. Therefore the cocking of hay is not now a common practice in most sections of this country.

However, it is probably wise to cock hay sometimes to lessen damage from rain. Hay is injured most by heavy rain when it is nearly cured. Therefore, if there is every prospect of a hard storm

If good weather continues, the curing should be completed in the windrow and the hay hauled to the barn or stack directly from the windrow. To avoid serious loss of leaves in dry climates, it may be necessary to handle the hay only early in the morning before it has become too dry.

When the weather is such that the hay cures rather slowly, it may be advisable in a few hours to turn the windrows partly over, in order to hasten the curing. Turning may also be necessary if the hay is wet by rain when in the windrow.

Hay crushers have been developed which pass the forage between rollers after it is cut by the cutter bar of the

at that time, it is a good plan to hurry and put the hay into large, well-made cocks. Unless the rain is unusually heavy, these will not wet through, there will be practically no loss from leaching, and the color and carotene content will be well preserved. When the weather clears and the outside of the cocks has dried, it may be necessary to open them somewhat to dry out the interior before the hay is stored.

401. Curing devices for very rainy districts.—In some sections of northern Europe, especially in Scotland, Norway, Sweden, and Finland, where the summer weather is cool, the humidity high, and rain very frequent, it is nearly impossible to cure hay satisfactorily in the field by ordinary methods. In these regions, after the hay is partly cured, it is generally put on tripods or other devices which allow the air to penetrate.

Similar methods are used to some extent in this country, especially in curing cowpea hay or peanuts in the southeastern states. All of these methods take much labor and are too expensive to be used where good hay can generally be made by ordinary methods.

A common method under such conditions is to cock the hay, after it is partly cured, on tripods, where it is left until dry enough for storage. The tripod consists of 3 poles, joined at the top, and generally with cross pieces at right angles to keep the hay off the ground. This permits making a large, well-ventilated cock that will contain as much as 500 lbs. or more of hay after curing. Sometimes single poles with crosspieces near the bottom are used instead of tripods. These are set in holes made in the ground. This method is often used in curing peanuts in this country. Another method used in some sections of northern Europe is to drape the hay in layers over the wires of temporary fences put up in the hay field.

402. From windrow to storage.—Several methods are used in getting hay from the windrow to storage. These include the hay-loader method, buck rakes, windrow balers, and field choppers, with the other equipment used in connection with these machines. Several experiment stations have conducted cost studies to determine the amounts of labor required and the other expenses per ton in handling hay by the various methods.[18] In these experiments the hay-loader method has generally been taken as the standard with which the newer methods have been compared. Some of the important results of these studies are summarized in the following articles.

No matter what method is used in handling and storing hay, good judgment should be used in putting the various kinds and qualities of hay in a place where they will be available when wanted, and not be covered with other hay. On a dairy farm, it is a mistake to put all the late-cut hay on top of the higher-quality, early-cut hay. If this is done, the cows may drop off severely in production in the fall when they get only the poorer hay.

403. The hay-loader method.—In the northeastern and north-central states the hay-loader method of handling hay is still common. When the hay is loaded with a hay loader, it is generally unloaded at the barn with a hay fork or hay slings and mowed away by hand. Sometimes the hay is run through a stationary hay chopper or silage cutter at the barn and blown into the barn. Occasionally, the long hay is blown into the mow by means of a hay blower, either manufactured for the purpose or converted from the blower on an old threshing machine.

When the hay is unloaded with a hay fork or slings, care should be taken to distribute it well in the mow and not leave it in large, compact masses where it falls from the fork or sling. Such masses are especially apt to heat badly, if the hay is not thoroughly dry.

The hay-loader method requires somewhat more man labor per ton than some of the newer methods, but the cost of equipment is much lower than with a windrow baler or field chopper. Except when the acreage of hay is large, the total cost per ton of handling hay by the hay-loader method may therefore be less

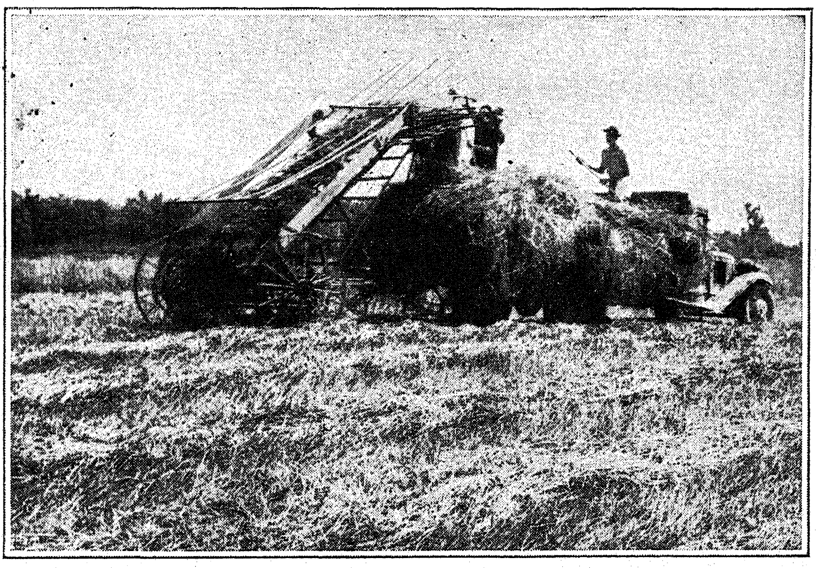
than when a field chopper or windrow baler is used.

Pitching hay on a load by hand requires more man labor per ton than loading it with a hay loader, and it is also much harder work.

404. The buck-rake, or sweep-rake method.—In the Great Plains and westward much hay is hauled from the windrow with buck rakes, or sweep rakes. Commonly the hay is stacked in the field by hay stackers or other mechanical devices. Some farmers in the sections of the country where hay is stored in barns or sheds also use the buck-rake method of handling hay. The hay is gathered up from the windrow with the buck rake and hauled on it to the place where it is to be stored. Here it is put in the mow with hay sling, grapple fork, or blower. The hay is too loose for successful use of a harpoon hay fork.

Where the distance from the hayfield to the storage place is not long, the buck rake is the cheapest method of handling hay. The amount of labor per ton is small and the cost of equipment is relatively low.

405. Baling hay from the windrow.—During recent years the baling of hay from the windrow with windrow balers, or pick-up balers, has greatly increased in this country. In some districts much hay is now baled from the windrow by custom balers. Hay of good quality, free from mold and of good color, can be made with the windrow baler if certain precautions are taken.



THE HAY-LOADER METHOD IS EFFICIENT

The hay-loader method of handling hay requires somewhat more man labor per ton than when a one-man windrow baler or a field chopper is used. However, this is offset by the low cost of equipment. (From New York State College of Agriculture, Cornell University.)

The hay should preferably be a little drier than is safe for storage of loose hay in a large mass.[19] The hay should certainly not contain more than 25 per cent water, and 20 to 22 per cent is better. If legume hay gets too dry before it is baled, the leaves will shatter badly. Otherwise, windrow baling saves the leaves well.

The hay must not be packed so tightly in the bales as is customary in baling hay that has gone through the

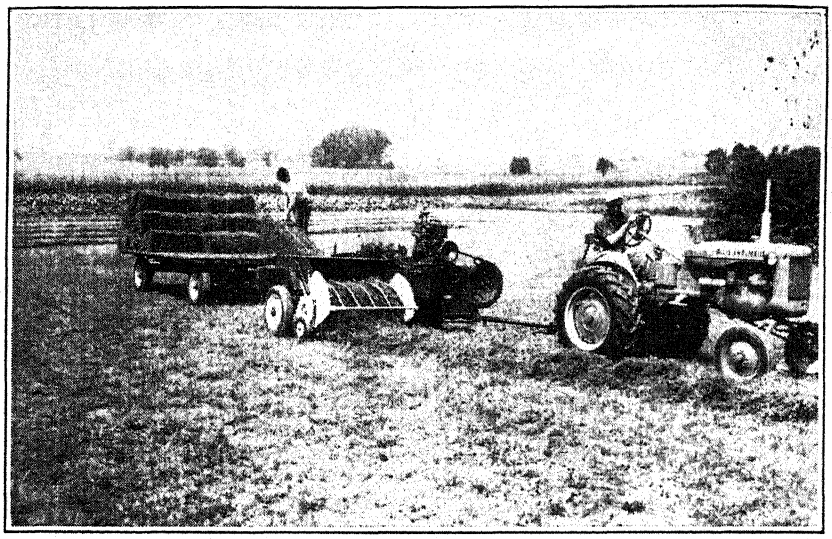
"sweat" in mow or stack. With a moisture content of 25 per cent, the bales should not weigh more than 8 lbs. per cubic foot. Drier hay can be packed a little tighter.

To allow ventilation in the pile of bales in a mow, rectangular bales should be placed on edge, with the fold edge of one bale next to the chaff edge of the next one and with the alternate layers at right angles. The bales should not be crowded closely together, but it is not necessary to leave a large space between them. All loose hay should be removed from the top of a layer of bales before the next layer is placed on it.

With the one-man balers the labor cost is somewhat less than with the hay-loader method, but because of the much greater investment, the total cost per ton may be higher, unless the acreage of hay is large. Where baled hay is to be sold, the windrow baler is especially advantageous.

Instead of lifting the bales by hand and loading them onto the truck, much labor can be saved by means of a bale chute, which delivers the bales to a truck towed behind the baler. Another way of saving labor in loading bales is by means of a bale loader. At the barn, time and hard work can be saved by the use of a bale elevator.

In the irrigated districts of the Southwest it is often difficult to prevent alfalfa hay from becoming so dry in the field that it shatters badly. High-quality hay may be made by putting it in large cocks while still tough, and then baling it from the cocks with a portable baler after it has cured sufficiently.



ONE-MAN WINDROW BALER SAVES LABOR

A one-man windrow baler with a device for loading the bales direct from the baler. (From New Holland Machine Co.)

406. Danger from baling wire.—In handling and feeding hay baled with wire, great care is necessary to prevent losses of cattle from baling-wire injury. Sharp pieces of wire consumed with the hay often may pierce the stomach and damage the heart or other vital organs. Cutting the wires should be avoided if possible. With windrow-baled hay the bales shrink sufficiently in curing so that the wires can easily be pulled off.

The wires should be put in a barrel or box, where they will not get into feed or manure. If wires get into the manure, they may be cut into dangerous pieces by the mower when a hay crop is harvested later.

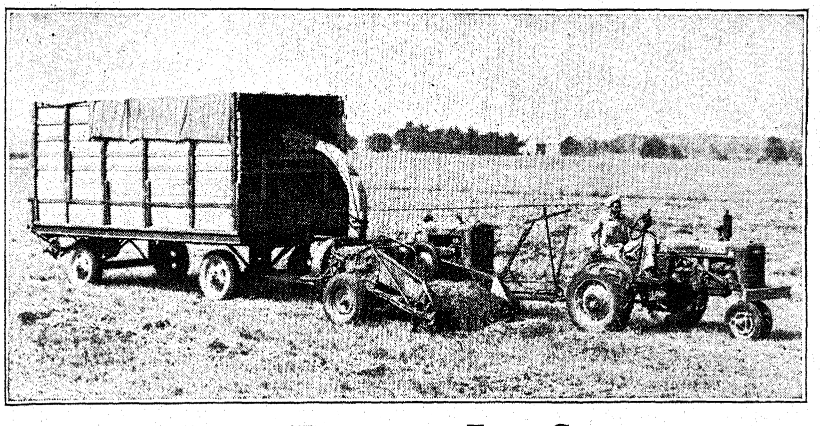
407. Chopping hay.—During recent years the use of field choppers, or forage harvesters, for handling hay from the windrow has greatly increased. The chopped hay is blown into a truck alongside or towed behind the chopper, and then at the barn is blown into the mow with a special blower. In semi-arid districts the chopped hay is often stacked in the open. Sometimes long hay is taken from the windrow to the barn and there chopped with a hay chopper or silage cutter which blows it into the mow.

Chopped hay is convenient to feed. However, the feeding value per ton of good-quality hay for cattle, sheep, or horses is not increased appreciably by chopping it, if the hay is fed in mangers or racks that prevent undue wastage. (92) There may be somewhat more advantage in chopping poorer hay.

Hay chopped fine is dusty and is much less palatable to cattle, sheep, or horses than hay chopped coarsely. Also, more power is required to chop hay fine, and the hay is more apt to heat badly when stored. Therefore the chopper should be set to chop the hay as coarse as possible.

For safe storage, chopped hay must be a little drier than is necessary with long hay. It has a greater tendency to heat unduly, because it packs much more densely and there is less opportunity for moisture and heat to escape. Chopped hay occupies only one-half to one-third as much space as long hay, and thus barn storage space is saved. However, care is necessary not to overload the joists in storing chopped hay, unless the barn has been built especially for such storage.

The hay should be distributed in the mow by adjusting the blower. It should never be tramped or packed, but should be allowed to settle itself. Otherwise, it is apt to heat in spots.



HANDLING HAY WITH A FIELD CHOPPER

When a field chopper is used, with suitable equipment for hauling and unloading the chopped hay, the amount of labor required per ton is very low. However, the cost of the equipment is high.

When a field chopper is used with suitable equipment for hauling and unloading the chopped hay, the amount of labor required per ton is very low. Though the investment in equipment is high, this method is economical when the acreage of forage handled by the chopper is sufficiently large to justify the expense. The cost per ton is reduced materially when a forage harvester is used not only to handle the hay, but also to harvest hay crops or corn for silage.

Chopped hay should not be stored in ordinary silos, unless it is considerably dryer than would be necessary in the case of uncut hay stored in a mow or

stack. Otherwise, it is apt to heat greatly and it may even char.

408. Barn-drying hay.—In areas where the weather is such that it is frequently difficult to make field-cured hay of good quality, the barn-drying method is often used. In this method partly-cured hay is dried by blowing unheated or heated air through it. A powerful fan blows air from outside the barn into a large duct constructed on the floor of the mow. From this, the air passes between the floor of the mow and a false slatted floor above it, or into a system of ducts or flues on the floor, and thence up into the mass of hay. This method is used both for partly dried long hay and for chopped hay. Sometimes baled hay is cured thus.

In this method the hay should, if possible, be at least half cured in the field, to bring the water content down to not more than 40 per cent. In suitable weather, it is better to cure it even a little more than this in the field, because it lessens the weight that must be handled and reduces the cost of power in barn drying. Hay with 35 per cent water is tough enough so that few leaves shatter.

Unless the curing is completed in a week or less, the barn-dried hay is apt to mold. It is therefore important to have a fan with plenty of air capacity. With a system that is properly constructed and operated, there is no danger of spontaneous combustion, as the temperature does not rise to a dangerous point.

In most barn driers the fan is driven by an electric motor. It is well to have the installation made so that the fan can also be run with a tractor in case there is a serious interruption of electric power.

In regions where the air is very humid at night, much better results are secured when the air is heated somewhat by an oil furnace or other means. This increases the cost, but makes it possible to obtain satisfactory results under difficult weather conditions.

In bad weather for haymaking, better hay can usually be made by this system than by ordinary field-curing methods. Satisfactory hay may even be made under conditions where it would be severely damaged or nearly worthless if field cured. On the other hand, in good hay-making weather, there is generally but little difference in quality between barn-dried and field-cured hay, except that barn-dried legume hay is apt to be more leafy and higher in protein, because it is stored before the leaves tend to shatter.

The advantages of the barn-drying method are more or less offset by the considerably increased cost, because of the expense of the equipment, the cost of power, and the increased labor in handling the heavy, partly-dried hay. Also, the capacity of a barn for storing hay is much lessened in this method, because the hay must not be stored in too great depth.

In bad haymaking weather, it is probably cheaper as a rule to make a hay crop into silage than to use the barn-drying method. The feeding value of the crop, especially the carotene content, is preserved even better in hay-crop silage. Also, good silage can be made when rains are so frequent that it would be difficult to cure hay in the field sufficiently for barn drying.

Barn-drying with unheated air does not avoid an appreciable loss of nutrients by fermentation during the curing process in the mow. In fact, a large part of the heat needed to evaporate the excess water from the partly-cured hay comes from the oxidation of nutrients that takes place. In tests by the United States Department of Agriculture, hay stored with 39 per cent of water lost 9.9 per cent of its dry matter in barn drying.[20] The loss was only 5.7 per cent with hay having 33 per cent of water. In New York trials the loss of dry matter in hay during barn drying and storage was 6.7 per cent.[21]

The carotene content of barn-dried hay is much higher when placed in the mow than for field-cured hay, but a large part is lost in the drying process through the fermentations, and later during storage. When fed in the winter, barn-dried hay will, however, usually have consid-

erably more carotene than field-cured hay cut at the same time. For example, in 6 lots of hay made at Cornell University, barn-dried hay cured without heat had 8.4 milligrams of carotene per pound of dry matter when fed in winter, while field-cured hay had only 3.8 milligrams.[21] In similar studies by the United States Department of Agriculture, barn-dried hay, air not heated, had 9.3 milligrams of carotene per pound of dry matter when fed, and field-cured hay 5.4 milligrams.[22] Though the carotene content of the field-cured hay was much lower in both studies, nevertheless it still had plenty to meet the needs of dairy cows.

409. Feeding experiments with barn-dried hay.—The comparisons of the value of barn-dried hay with that of field-cured hay made in reasonably good weather from the same crop and cut at the same time have shown that there is usually little, if any, difference in the palatability and the actual feeding value of the two kinds of hay per pound. The advantages of barn-drying are therefore the following:

Barn-drying helps to take the gamble out of hay making in humid regions, especially in making the first cutting of hay. It is hence possible to make hay of good quality earlier in the season than by field curing. Such earlier-cut hay definitely has a higher value per ton than field-cured hay made later. Also, as has been pointed out previously, the nutrient losses and the losses of dry matter are somewhat less than in field curing, even in good weather. Thus, somewhat more hay is secured per acre for feeding. These advantages can also be secured when the crop is made into silage by good methods.

410. Barn-dried hay for dairy cattle.—Barn-dried alfalfa or mixed grass-and-legume hay was compared with field-cured hay, made from the same crop and cut at the same time, in 6 New York experiments.[21] The same amount of concentrates was fed with the two types of hay. At the time of feeding, the barn-dried hay was generally greener in color, and it usually graded about one U.S. Grade higher than the field-cured hay. There was no appreciable difference in the palatability of the hays, and on the average the cows ate fully as much hay when fed the field-cured hay. The daily yield of 4 per cent fat-corrected milk averaged 31.5 lbs. on the barn-dried hay and 31.1 lbs. on the field-cured hay.

In 4 of the trials field-cured windrow-baled hay was compared with the other hays. There was no significant difference in hay consumption or in milk production on the different types of hay.

In experiments during 3 years by the United States Department of Agriculture, alfalfa was made into barn-dried hay, field-cured hay, and wilted alfalfa silage.[22] One year the field-cured hay was damaged somewhat by rain, but the weather was favorable for hay making in the other seasons. The good field-cured hay was as satisfactory for dairy cows as the barn-dried hay or the alfalfa silage, but the field-cured hay that had been damaged by rain was lower in value.

In these studies, which extended over 6 crops, 81 per cent of the original dry matter in the alfalfa was saved for feeding by barn drying without heat, 85 per cent by barn drying with heated air, 82 per cent by ensiling the crop, 79 per cent by field curing in good weather, and only 63 per cent by field curing in bad weather.

Similar results have usually been secured in experiments with dairy cows by the Indiana, Massachusetts, Michigan, and Virginia Stations,[23] and in trials with dairy heifers by the Maine, Ohio, Tennessee, and Vermont Stations.[24] In a Michigan trial in which the barn-dried hay was cut 2 weeks earlier than the field-cured hay, it was definitely superior to it.[25]

411. Barn-dried hay for other stock.—Field-cured hay was fully equal to barn-dried hay for wintering beef steers in a Maine trial.[26] In a Nebraska experiment field-cured alfalfa hay gave about as good results as barn-dried alfalfa or dehydrated alfalfa pellets when fed as the protein supplement for wintering beef calves.[27]

Colts in an Iowa test decidedly preferred barn-dried hay to field-cured hay that had heated badly in storage and had become musty.[28]

412. Brown hay.—Several years ago there was interest among farmers in making "brown hay" when weather conditions were unfavorable for making good hay by the usual methods. Because of the very heavy losses of nutrients in brown hay, and the uncertainty of securing a fair product, most of the brown hay now made in this country is produced accidently, and not intentionally.

In this method the forage is allowed to wilt until the water content has been reduced to about 50 per cent and then is well packed in a stack. Extensive fermentation occurs and much heat is developed. If all goes well, the temperature does not rise above 175° F., and the heat drives off the water in the mass.

The loss of dry matter in the fermentations is often as high as 40 per cent, and the digestibility is much decreased.[29] The product will vary in color from dark brown to nearly black, depending on the degree of fermentation. The darker the color, the lower is the feeding value. Hay that is nearly black is worth but little.

Brown hay of good quality is well liked by stock, but it is very low in vitamins, and should therefore not be the only roughage for stock throughout the entire winter. In experiments brown alfalfa hay was about equal to good green alfalfa hay for fattening steers and fattening lambs, but it was distinctly inferior to green alfalfa hay for dairy cows.[30]

413. Salting hay; so-called "preservatives."—Some farmers believe that sprinkling 10 to 20 lbs. of salt on each ton of rather-damp hay helps to prevent mold or undue heating. Salting may perhaps make poor hay somewhat more palatable, but experiments have shown that it is no insurance against spoilage, or even against spontaneous combustion if the hay is much too damp.[31] In fact, too great reliance on salting may be dangerous. The only safe plan is not to store hay unless it is dry enough for safety.

So-called "preservatives," consisting chiefly of ordinary baking soda, have been sold with claims that, due to liberation of carbon dioxide, all heating or molding would be prevented by sprinkling 1 to 5 lbs. of the compound on each ton of under-cured hay or threshed grain. There is no sound basis for such claims, because in the normal heating of new hay or grain when stored, a far greater amount of carbon dioxide is produced than could be formed from the small quantity of the "preservative."

In experiment station tests of such compounds, they have not reduced the spoilage of damp hay.[32]

414. Spontaneous combustion.—If hay or other dry forage containing too much moisture is put into a mow or stack, rapid fermentations take place in which a large amount of heat is produced. In a large mow or stack most of this heat is retained in the mass, causing a rapid rise of temperature. In these fermentations highly unstable organic compounds are apparently formed which are readily oxidized.[33]

At temperatures of 150° to 175° F. all bacteria or molds are killed or made inactive, but the oxidations continue, and the mass may become extremely hot. Finally, the hay begins to char and spontaneous combustion may occur and the mass burst into flames. This generally happens a month or 6 weeks after the hay is stored, but it may occur sooner.

The only way to avoid such loss is never to store hay in a large mass unless it is thoroughly cured. Chopped hay must be drier than long hay for safe storage. For safety, mows should be inspected at least twice a week during the first 2 months after the hay is stored. If hay in a mow or stock heats badly within 2 or 3 days after storing, and pungent odors, with much vapor, are given off, it should be removed at once and spread out to dry. Removing the hay later may only hasten spontaneous combustion.

If danger threatens, it is wise to take the temperature down in the hot

spots in the hay, by lowering, in a pipe driven into the hay, a thermometer that reads up to 200° F. If the temperature goes above 160° F., there is grave danger, and at 175° to 185° fire pockets may be expected. Before removing the hay then, a fire department should be called, if available, for the hay may burst into flame when the air reaches it.

Injecting into a mass of hot hay carbon-dioxide gas under pressure, from a cylinder of the compressed gas, such as is used in soda fountains, or from dry ice, cools the hay and helps prevent fire.

Stacks should never be built on old, rotten stack bottoms. Baled hay, grain in the sheaf, or other heavy material should not be put on top of hay in a mow which is going through the sweat, for it will prevent the escape of heat and gases. Crops upon which rain has fallen should receive extra care, and should not be housed until completely dry.

415. Measurement and shrinkage of hay.—Farmers, ranchers, and hay dealers buy and sell large quantities of hay in the stack according to the estimated weight. The stack is measured and the volume and tonnage are then computed by one of several rules in common use. The density of the hay and therefore the number of cubic feet required per ton are affected by many factors. Hay that was stored when slightly damp will be more compact than that which was very dry. The coarseness of the hay also affects its density.

The following rules are recommended by the United States Department of Agriculture for estimating the tonnage of hay in stacks, from the volume in cubic feet.[34] For hay 30 to 90 days in the stack, 485 cubic feet per ton for alfalfa; 640 for timothy and timothy mixed hay; and 600 for wild hay. For hay over 90 days in the stack, 470 cubic feet per ton for alfalfa; 625 for timothy and timothy mixed hay; and 450 for wild hay. The same approximate figures may be used for hay in a mow. In Idaho tests only about 150 cubic feet of stacked chopped alfalfa hay were required to make a ton.[35]

The volume of hay in a mow can readily be computed, but it is more difficult to determine the volume of a stack. Different rules for estimating this have been used in various sections of the country. The following are recommended by the United States Department of Agriculture after much investigation on the subject:[34]

The volume of a rectangular or oblong stack in cubic feet is:

For low, round-topped stacks:
$$(0.52 \times O) - (0.44 \times W) \times W \times L$$
For high, round-topped stacks:
$$(0.52 \times O) - (0.46 \times W) \times W \times L$$
For square, flat-topped stacks:
$$(0.56 \times O) - (0.55 \times W) \times W \times L$$
The volume of a round stack is:
$$(0.04 \times O) - (0.012 \times C) \times C^2$$

In these formulas O is the "over" (the distance from the base on one side of the stack, over the stack, and to the base on the other side); W is the width; L is the length; and C is the circumference of a round stack, or the distance around it. In measuring a round stack, the "over" should be an average of two measurements made at right angles to each other.

Hay stored in the mow will shrink in weight, due to drying out and also to fermentations taking place during the sweating process, in which nutrients are broken down into carbon dioxide and water. The shrinkage in weight will vary, depending on the water content of the hay when placed in the mow, and may reach 20 per cent or over. The losses of dry matter in hay during storage have been discussed previously. (**396**)

When hay is stacked, the shrinkage in weight is greater than in a mow, since the outside of the stack is exposed to the weather. A stack 12 feet in diameter has about one-third of its contents in the surface foot.

The difference in the loss of dry matter in stacked hay and in that stored under cover will depend on how well the stack is made, on its size, and especially on the climatic conditions. West Virginia trials show that in hay stored in well made stacks until winter the loss of dry matter was not much greater than

in hay stored in a barn, and the feeding value per ton of hay fed was nearly as high.[36]

III. Dehydrated Hay or Other Forage

416. Dehydrated hay.—More than a million tons of dehydrated hay, mostly alfalfa, are now produced commercially each year in this country. This dehydrated hay, made in dryers of various types, is used chiefly as a vitamin supplement in rations for poultry and swine, and to a lesser extent in calf meals and for other stock. In addition to alfalfa, other hay crops or other forages are sometimes dehydrated for these purposes.

The forage is first chopped and then passed through the drier. Here it is exposed by various methods to a current of hot air or a mixture of hot air and gases from an oil burner or furnace. Sometimes the green material is partly dried in the field to reduce the cost of dehydrating it, but this lowers the carotene content somewhat.

Though the temperature of the hot gases may be over 1,000° F., the forage itself does not become so hot as to be injured in a good drier. This is due to the cooling effect produced when the water evaporates from the plant tissues. In this method there is no loss of leaves, and therefore a maximum yield of dry matter and of protein and other nutrients is secured. The green color is also well retained.

Dehydration preserves the feeding value of a hay crop decidedly better than making it into field-cured hay or even making it into barn-dried hay or silage. However, the cost per ton of dry material is much higher. This is because of the large cost of the dehydrating plant, the considerable amount of fuel required for each ton of dried hay, and the expense for power and labor. Where good hay can be made by ordinary methods, it is therefore not usually economical to dehydrate hay crops for feeding to dairy cattle, beef cattle, sheep, or horses. In regions where rains are so frequent in summer that much of the field-cured hay is damaged, in spite of good management, it is generally much cheaper to make hay crops into silage, or to use a barn-drying method.

In experiments at the Vermont Station there was a loss of only 5.5 per cent of the dry matter in dehydrating hay and storing it until winter.[37] When the same crops were cured in the field in reasonably good weather and stored until winter, 23.4 per cent of the dry matter was lost in the case of legume hay and 9.5 per cent with timothy hay.

In recent experiments by the United States Department of Agriculture the loss of dry matter in dehydrated alfalfa from field to manger in the winter was only 3.3 per cent when the dehydrator was operating properly.[22] Compared with this, the average loss in field-cured hay, made in good weather, was 21 per cent; in barn-dried hay with heated air 15 per cent; and in wilted silage 17 per cent.

417. Nutritive value of dehydrated hay.—Dehydrated alfalfa is used much more commonly than field-cured alfalfa meal as a vitamin A supplement because the carotene content is usually much higher than in good field-cured hay. Dehydrated alfalfa is also generally richer in other vitamins.

In the Vermont experiments dehydrated hay had more than 3 times as much carotene when fed in the winter as did the field-cured hay. In the experiments by the United States Department of Agriculture the difference was even greater between dehydrated hay and field-cured hay. The dehydrated hay when fed had nearly twice as much carotene as did barn-dried hay cured with heated air. On the other hand, wilted alfalfa silage, when fed, had slightly more carotene per pound of dry matter than did the dehydrated hay.

Differing greatly from its high content of carotene, dehydrated hay usually has but little vitamin D, which is formed in field-cured hay by the action of the ultra-violet rays in sunlight. (201) Consequently, dehydrated hay cannot serve as a vitamin D supplement in stock feeding. This fact must be borne in

mind, especially in using dehydrated alfalfa as a vitamin supplement for swine in winter.

In poultry feeding the fact that dehydrated alfalfa has little vitamin D is not important. This is because the kind of vitamin D in field-cured hay has very low efficiency for poultry. (202) Also, the vitamin D requirements of poultry are so high that a special vitamin D supplement is practically always added to the ration, except perhaps for birds outdoors on pasture.

It was found in Vermont experiments that dehydrated hay contained only 4 per cent more total digestible nutrients per 100 lbs. than did field-cured hay made in reasonably good weather from the same crop.[37] The dehydrated hay contained somewhat more total protein than the field-cured hay, because there had been no loss of leaves. However, the protein was less digestible in the dehydrated hay, apparently because of the effect of the heat in dehydration. As a result, the dehydrated hay contained slightly less digestible protein, on the average.

418. Feeding experiments with dehydrated hay.—The use of dehydrated alfalfa or other dehydrated forage as a vitamin supplement for the various classes of stock is discussed in Chapter XVI and in the respective chapters of Part III. Experiments are also summarized there in which dehydrated alfalfa has been used as a protein supplement to replace part or all of the high-protein supplements in rations for dairy cattle, beef cattle, and sheep, or to replace part of the concentrates fed these animals.

As a substitute for good field-cured hay made from the same cutting, dehydrated hay has a slightly higher feeding value per ton. However, the difference in value is usually more than offset by the greater cost of dehydration. Dehydrated hay of course has a much greater value per ton than field-cured hay of poor quality.

Dehydrated hay or pellets made from ground dehydrated hay should not be used to replace all the hay or hay and silage for dairy cows. It is shown in Chapter XXV that this may decrease rumination and considerably lower the fat content of the milk. (1052) In an experiment by the United States Department of Agriculture, when heifers were fed pelleted alfalfa as the sole ration the fat test of the milk was very low.[38]

When used as a supplement to pasture for dairy cows, dehydrated soybean hay produced considerably less milk than when the cows were fed a good concentrate mixture, or grain mixture, to supplement pasture.[39]

419. Dehydrated young forage not a concentrate.—On account of the high nutritive value of young grasses and legumes, experiments have been conducted to determine whether such forage, when dehydrated, could be used satisfactorily as a substitute for grain and other concentrates. Appendix Table I shows that at the pasture stage mixed grass and clover, dried to a hay basis, contains only 19.7 per cent fiber and is very rich in protein. In comparison with this, hay made from crops cut at the usual stage of growth generally has 28 to 30 per cent fiber. The dried immature forage is considerably more digestible than hay and supplies 66.7 lbs. total digestible nutrients per 100 lbs. However, it is lower than most concentrates in total digestible nutrients and especially in net energy.

When dehydrated young grass has been substituted for part of the concentrates usually fed, the production of good dairy cows has been well maintained in some experiments, but it was decreased appreciably in a Washington trial when dehydrated young grass-legume mixture replaced 15 per cent or more of the concentrates usually fed.[40] When the dehydrated grass has replaced all the concentrates for dairy cows and the usual amounts of hay or hay and silage have been fed, the production has been considerably lowered. The ration was then so bulky that the cows could not consume sufficient nutrients to keep up the maximum milk flow.

In a Vermont test cows fed a reduced amount of hay and silage, with

a large allowance of dehydrated grass (greater than the weight of concentrates usually fed), produced as much milk as on a normal ration of concentrates, hay, and silage.[41] The dehydrated grass was also satisfactory as a silage substitute.

On account of the high cost of harvesting the immature grass at frequent intervals and of dehydrating the watery material, the use of such dehydrated grass as a substitute for concentrates does not appear to be practicable under ordinary conditions.

420. Pelleted dehydrated hay.—Some dehydrated alfalfa is pelleted in pelleting machines. Pelleted alfalfa is much less bulky than alfalfa meal and also it can be shipped in bulk. Therefore when the product is shipped a long distance, the cost of shipment may be enough less to more than cover the cost of pelleting. The use of alfalfa pellets for the various classes of stock is discussed in the respective chapters of Part III.

QUESTIONS

1. What characteristics does high-quality hay have?
2. What have experiments shown concerning the relative value of good and poor hay?
3. Discuss the importance of cutting hay early.
4. How high can the water content of hay be for safe storage? How can a farmer tell when hay is dry enough for storage?
5. Discuss the following losses of nutritive value in haymaking, and tell how each can be minimized: (a) Losses by shattering; (b) by fermentation and bleaching; (c) by leaching.
6. What is the approximate total loss of dry matter during field curing in fairly good weather and in storage in the mow for legume hay; for grass hay?
7. Discuss the curing of hay in swath and windrow.
8. Discuss the effects of mowing hay at various times of day.
9. Under what conditions may it be wise to put hay in cocks?
10. What devices are used in curing hay in very rainy districts?
11. Discuss the merits of the hay-loader method of storing hay.
12. Under what condition is the buck-rake method most efficient?
13. Discuss baling hay from the windrow.
14. What danger is there in feeding baled hay?
15. Discuss chopping hay as it is stored.
16. What are the advantages and disadvantages of the barn-drying of hay?
17. What have experiments shown concerning the relative value of barn-dried and field-cured hay?
18. Why is not the making of brown hay advisable?
19. What is the effect of adding salt to hay as it is stored; of using a preservative consisting chiefly of soda?
20. How may losses from spontaneous combustion be prevented?
21. Compare the nutrient losses in dehydrating and field curing hay. Why is not dehydrated hay used extensively for dairy cattle, beef cattle, sheep, or horses?
22. What is the relative carotene and vitamin D content of dehydrated and field-cured hay?
23. Discuss the use of dehydrated hay or young forage as a substitute for concentrates.

CHAPTER XV

SILAGE AND CROPS FOR SILAGE

I. The Ensiling of Forage Crops

421. Advantages of silage.—In most of the leading stock-farming districts of the United States silage is a feed of great importance. This wide use of silage is the result of the following advantages:

1. The use of silage generally makes it possible to keep more stock on a certain area of land.

Over most of this country either corn or the sorghums surpass other forage crops in yield of total digestible nutrients per acre. They may readily be made into excellent silage, and a far greater feeding value is secured when these crops are used for silage than when they are fed as dry fodder or when the grain is removed and the grain and stover are fed separately.

During recent years the making of hay-crop silage, or "grass silage" has increased greatly in this country. It has been shown in the previous chapter that the losses of nutrients are less when a hay crop is made into silage by a good method than when it is made into field-cured hay. (398) The difference is especially great in the case of carotene.

2. At a low expense silage furnishes high-quality succulent feed for any season of the year. In winter, silage is far cheaper than roots, and in summer it is much more economical than a succession of specially grown soiling crops.

3. Crops may be ensiled when the weather does not permit curing them into hay or dry fodder.

4. Silage, even from plants with coarse stalks, such as corn and the sorghums, is eaten practically without waste. On the other hand, a considerable part of dry corn or sorghum fodder is usually wasted, even if it is of good quality.

5. Weedy crops, which would make poor hay, may produce satisfactory silage, and the ensiling process kills many kinds of weed seeds.

6. The crop from a given area can be stored in less space as silage than as dry forage.

7. When a corn or sorghum crop is ensiled, the forage is removed from the land early, so that it may be prepared for another crop.

8. In areas where there is considerable damage from the European corn borer, cutting the stalks close to the ground and then ensiling the crop is one of the best methods of controlling the pest.

The importance of silage in this country is shown by the fact that over 6,000,000 acres of corn and 1,000,000 acres of sorghums are grown annually for silage. In addition, considerable acreages of hay crops are ensiled, data for which are not available.

422. Value and use of silage.—Because of the importance of silage, its value and use for the various classes of stock are discussed in detail in the chapters of Part III. Information is also given in the following chapters about the most important silage crops.

Apart from the nutrients it contains, good silage has certain merits not possessed by most dry roughages. It is highly palatable, and therefore stock will usually eat more roughage on the dry basis, when fed silage in addition to hay or other dry forage, than when receiving only dry feed. This often makes possible a considerable saving in the amount of concentrates required for good production.

Silage is slightly laxative. This is especially beneficial when little or no legume hay is fed. If cattle or sheep have only dry non-legume roughage dur-

ing the winter they are apt to become constipated and unthrifty.

Stock are not injured by the considerable amounts of silage acids that they consume when they are fed silage continuously for a long time. The organic acids in silage are similar to those normally produced in the digestive tract of ruminants in the digestion of the fiber and pentosans of the feeds through bacterial action. These acids are used by the animal for food in the same manner as are the sugars. (As mentioned later, the mineral acids used in making phosphoric acid or A.I.V. silage should be neutralized by feeding ground limestone or a similar substance.)

SAVING ALL OF THE CORN CROP BY ENSILING IT

When the corn crop is ensiled at the proper stage of maturity, the full value of both grain and stover is secured for dairy cattle, beef cattle, and sheep.

Silage is used most extensively for the feeding of dairy cattle, especially dairy cows. Cows will generally produce more milk on a ration containing both silage and good hay than when only dry roughage is fed. The only exception is when they have an abundance of excellent legume or mixed legume-grass hay of considerably better quality than the average. Silage is particularly important for milk production when the available dry roughage is rather inferior. To avoid injury to the flavor of milk, silage should be fed after milking, and it should not be left in the stable.

Silage is just as useful and economical for beef cattle and sheep as it is for dairy cows. In fact, as is pointed out in Chapter XVII, the value per ton of well-matured corn silage for fattening cattle or lambs is even slightly higher, in comparison with that of hay, than it is for dairy cows. Silage aids in keeping beef breeding cows and breeding ewes in thrifty condition during the winter, as well as being a cheap feed for them.

Good silage may also be used in a limited way with idle horses and those not worked hard in winter, especially brood mares and colts. Silage is used but little for swine or poultry. Well-cured legume hay, particularly alfalfa hay, is better as a vitamin supplement for them.

Only as much silage should be supplied as will be cleaned up at each feed-

ing. Care should be taken to remove any waste, for it spoils in a short time on exposure to the air. Frozen silage must be thawed before feeding. Spoiled, moldy silage should be discarded, and one should be especially careful not to feed such silage to horses or sheep, because they are much more apt to be injured by it than are cattle. Silage which is unusually sour may cause digestive disturbances with sheep.

The amounts of silage commonly fed per head daily to the various classes of stock are about as follows:

Dairy cows, 30 to 50 lbs. for those in milk, with somewhat less for dry cows; dairy heifers, 12 to 20 lbs.; beef breeding cows, 30 to 50 lbs.; fattening 2-year-old steers, 25 to 30 lbs. at the beginning of the fattening period, the allowance decreasing as they fatten until only 10 to 15 lbs. are fed; fattening calves, from 10 to 20 lbs. at the beginning of the feeding period to 8 to 10 lbs. or less during the latter part; brood mares and idle horses, 15 to 30 lbs.; breeding ewes, 2 lbs. per 100 lbs. live weight (sometimes more is safely fed); fattening lambs, 1.5 to 3.0 lbs.

423. Silage for summer feeding.—Many farmers who fully appreciate the value of silage for winter feeding do not realize its value for supplementing dried-up pastures in the summer. It is also economical as a partial substitute for pasturage on high-priced land where all the stock possible must be kept per acre. Silage is generally much cheaper and more satisfactory than growing a succession of green soiling crops for these purposes. (**386–387**)

Silage can be used for summer feeding only if enough animals are fed to use 2 inches or more of silage daily from the entire surface of the silo, so as to prevent spoilage.

424. Economy of silage.—Numerous experiments have proved that silage is more economical and efficient than dry corn or sorghum fodder for dairy cattle, beef cattle, and sheep. There is, however, some difference of opinion as to whether silage is actually a cheaper feed than good hay.

The table in the following chapter shows that in the United States corn silage furnishes twice as much total digestible nutrients per acre as does clover-and-timothy hay, and 31 per cent more than does alfalfa hay. (**450**) These facts are of great importance to the farmer who desires to produce as much feed as possible on his farm.

In cost-accounting studies in the corn belt states, the cost per ton of corn silage, including ensiling the crop, has usually been about 30 to 40 per cent of the cost per ton of producing alfalfa hay or mixed hay. Under such conditions there is no question but what corn silage is a very economical feed, in comparison with hay. Numerous experiments have shown that corn silage is worth 33 to 40 per cent as much a ton as good hay for dairy cows and fully one-half as much as such hay for fattening beef cattle and sheep.

Even where the cost of silage, as found in cost-accounting studies, is fully one-half as much per ton as that of good hay, silage may still be an economical feed. This is because other factors must be considered than merely the cost per ton as found in such investigations.

First, all labor is valued at a uniform price per hour in such studies, regardless of whether it is in a rush season or not. When both corn silage and hay are produced, the demand for labor is distributed much better than when only hay is used for winter roughage. Therefore, the need of extra hired labor during hay-making may often be avoided.

The growing of a cultivated crop, such as corn or sorghum for silage, may have a special value in the crop rotation for the control of weeds.

In humid regions a considerable part of the hay crop will often be injured by rain, in spite of good management. It cannot be assumed therefore that the average hay actually fed on stock farms is of a high market grade. Much of it is, in fact, decidedly inferior. On the other hand, corn or sorghum silage is generally of high quality, if even moderate care is taken in ensiling the crop.

Last, but not least, it is often difficult in humid districts to cure, without

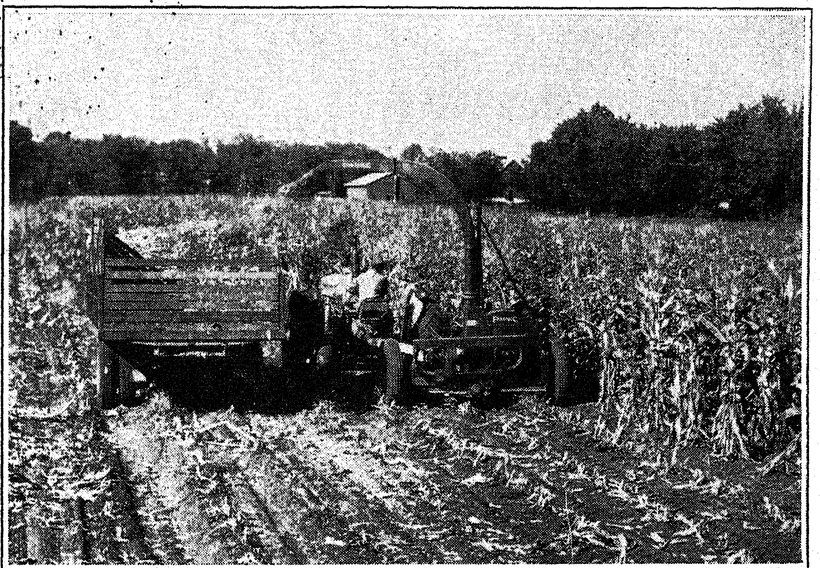
serious damage from rain, a large acreage of hay before it becomes too mature. This difficulty is much greater when hay is the only roughage than if silage is also produced.

Considering all of these factors, we can conclude that silage is an economical feed for cattle and sheep over most of the United States. However, in the irrigated districts of the West there are many areas in which the cost of producing high-quality alfalfa hay is very low in comparison with the cost of silage. Here hay may be a decidedly more economical feed.

The cost per ton of silage will obviously depend largely on the yield per acre. Corn or sorghum for silage should therefore be grown on land well adapted to the crop, and the field should be so fertilized and tilled that it will produce a large yield per acre.

The cost of ensiling the crop should be reduced as much as possible by using efficient methods. Where a corn binder is used for harvesting the crop, a bundle elevator and low-rack wagons save much labor. In ensiling the crop, time can be saved by keeping the cutter knives sharp and properly adjusted, and by running the cutter at the proper speed.

Where the acreage of silage and hay crops is large enough to warrant the expense for the equipment, the field chopper method of harvesting is most economical. (407)



HARVESTING CORN FOR SILAGE WITH A FORAGE HARVESTER

The expense of the equipment is distributed, when a forage harvester is used both for harvesting corn for silage and also for chopping hay from the windrow or for hay-crop silage.

425. How ensiling preserves green forage.—When green forage from a suitable crop is placed in a compact mass in a silo the following changes take place which convert it into silage: [1] For a time the living plant cells continue to respire, or breathe, rapidly using up the oxygen in the air entrapped in the mass and giving off carbon dioxide (carbonic acid gas). Within 5 hours practically all the oxygen has disappeared, and this prevents the development of molds, which are unable to grow in the absence of oxygen.

Acid-forming bacteria multiply enormously in the silage, and at the end of 2 days each gram of silage juice (about

one-fourth of a teaspoonful) may contain many billions of bacteria. These bacteria attack the sugars in the green forage, producing organic acids, chiefly lactic acid (the acid of sour milk), with some acetic acid (the acid of vinegar), and traces of other acids and also of alcohol. The production of acid is the most important change in the process, for acidity prevents the growth of undesirable bacteria, such as cause rotting, or putrefaction.

When enough acid has been formed, the fermentation is checked, and finally the action practically ceases. If air does not gain entrance, the silage will then keep for long periods with but little change. Instances are on record where corn silage 12 years or more old has been of satisfactory quality. If air does penetrate, as at the top of the silo or adjacent to a crack in the wall, mold will grow and destroy the acid. Putrefactive bacteria can then develop and cause further spoilage.

Corn or sorghum forage makes the best silage when the dry matter content is not less than about 27 or 28 per cent. To make good-quality silage from hay crops, such as alfalfa or grass, without a preservative the dry matter content should be 30 to 35 per cent. If the forage has less dry matter, there will be considerable loss of juice, and the silage is apt to be of poor quality unless a preservative is added, as described later.

If the percentage of water in the silage is too high, an undesirable type of fermentation is apt to occur, in which strong-smelling butyric acid is formed, instead of the much more palatable lactic and acetic acids. If the forage is too dry, it is apt to mold.

While the sugars are the chief compounds acted upon by the bacteria in the acid fermentations, the starch and pentosans may be attacked to a limited extent. However, the amount of acid developed in the silage depends largely on the percentage of sugar in the ensiled crop. If the forage is very high in sugar, as in the case of very immature corn or sorghum, so much acid may develop that the silage will be unpalatable to stock. Also, the feeding value will be lowered, because there will be a greater loss of nutrients in the fermentations. Normally the amount of acid in good corn silage is not greater than 1.0 to 2.4 per cent of the total weight.

In addition to the acids, some ordinary or ethyl alcohol is produced and also traces of other alcohols. The alcohols largely combine with the acids to form compounds that aid in producing the characteristic aroma of good silage. Yeast cells develop in the silage to some extent in the early stages of the process, but are relatively unimportant.

In silage formation the proteins in the green forage are broken down or digested to a considerable extent, probably by the enzymes in the plant cells. Such changes are similar to those that occur when proteins are digested into simpler compounds in the animal body, and therefore the action is not detrimental. However, in poorly preserved silage made from protein-rich hay crops, further break-down of protein may occur, resulting in considerable loss.

During the fermentations in silage, the temperature rises somewhat, but if the mass is well compacted, so that very little air is present, the temperature in the interior of the silo rarely exceeds 100° F. The changes are therefore far less extensive than those which take place in the making of brown hay. (412)

Very rarely, many spots of rotten silage occur in the midst of good silage. Such spoilage can be produced by certain bacteria which are not checked by the acidity or the lack of oxygen, but instead destroy the acid and rot the silage.[2] Where there has been this trouble, it is recommended that the silo walls be cleaned and painted with hot tar before filling, in order to kill the bacteria.

426. Efficiency with which silage preserves nutrients.—If a forage crop is ensiled in a large, well-made silo, the losses of dry matter and digestible nutrients are slightly less than when the crop is made into hay or dry fodder, even if the weather is satisfactory for field curing.[3] This is true for corn or sorghum forage and also for hay crops,

such as alfalfa or grasses. In poor weather for field curing, the losses will be much greater in hay or dry fodder than in silage. The carotene content of the green crop is generally preserved much better in silage than in hay or dry fodder.

The chief loss of nutrients in silage is through the oxidations that take place in the normal fermentations and other changes which occur in the silage process. In these changes a part of the nutrients (chiefly the sugars) is oxidized to carbon dioxide and water and thus lost. This loss should not amount to more than 5 to 10 per cent of the dry matter of the crop, if it is ensiled in a deep, well-built, cylindrical silo by a good method. When the mass of forage is not well compacted, as in a shallow silo, this loss may be much greater.

In addition, there is a loss through the spoilage of silage at the top of the silo, unless feeding begins as soon as the filling is completed. In a shallow silo, the percentage loss through this top spoilage is much greater than in a deep silo, because the forage that spoils at the top represents a greater proportion of the entire weight.

In a silo that is at least 30 feet deep, the top spoilage should not exceed more than 4 to 6 per cent of the dry matter. The top spoilage can be kept to a minimum by one of the methods of covering the surface which are mentioned later. (444)

If the forage is too high in water content when it is ensiled, a third loss will occur in the juice that runs out. The loss by this means should not exceed 1 to 3 per cent of the dry matter in the case of corn or sorghum forage that has reached the proper stage of maturity, or in the case of a hay-crop that has been slightly wilted before it is ensiled.[4]

The loss by seepage will be considerably higher if the forage is too watery. When the excess juice cannot escape from silage that is high in water, the silage will often be very sour and less palatable than that from crops lower in water.

In silos at least 30 feet deep, the total loss of dry matter should not exceed 10 to 15 per cent in corn or sorghum silage, if reasonable care is taken to reduce the surface spoilage and if there is little or no loss of juice. This loss is appreciably lower than the loss of dry matter that usually occurs when corn or sorghum forage is cured as dry fodder, or when a legume hay crop is made into hay by ordinary methods. (To determine the dry matter content of silage accurately, it is necessary to correct for the loss in ordinary drying of volatile nutrients, such as some of the organic acids.[5] Often this has not been done, and losses of dry matter have been reported which are too large.)

Even when cured in well-made shocks, corn fodder or stover standing in the field for a few months loses at least 15 per cent and usually 20 per cent or more of the dry matter it contains, because of weathering and fermentations which gradually waste the forage.[6] With unfavorable conditions the wastage is much greater. The losses are chiefly in the most valuable parts of the plant—the protein, sugar, and starch—which are less resistant and more soluble than the fiber.

The loss of dry matter in hay-crop silage is usually somewhat greater than in corn or sorghum silage. However, it should not be more than 20 to 25 per cent, if a good method is used and undue loss by seepage is avoided.

It has been shown in the previous chapter that in fairly satisfactory hay-making weather the loss of dry matter in making and storing legume hay by good field-curing methods may total 20 to 30 per cent. (398) In rainy weather the loss will be considerably greater.

427. Crops for the silo.—To make silage, a green forage crop must have certain qualities. First, it must be neither too dry nor too high in water content. If it is too dry, it will not pack well in the silo, and enough air will remain to permit the development of mold. If the forage is too high in water, the silage is apt to be very sour or it may even spoil.

It is essential that there be enough acid in the silage to prevent the growth

of undesirable bacteria that cause rotting or putrefaction. The forage must therefore contain a sufficient amount of sugar, or else one of the special methods must be used which are described later.

To make the best silage, the forage crop should have solid stems, so that only a small amount of air will remain in the mass after it has settled. In the case of the hollow-stemmed small grains, the cut forage must be tramped with especial care to force out as much air as possible.

made from a true grass, such as timothy; from a legume, such as alfalfa; from a mixture of legumes and grasses; or from a green cereal, such as oats. The author prefers the term hay-crop silage, as it is more exact and correct.

The special methods used in making hay-crop silage are described in the following articles. Various other kinds of silage are discussed in the later chapters, including silage made from pea vines from canning factories, sweet-corn cannery waste, green sweet corn stover, soft

A BUNDLE ELEVATOR SAVES LABOR

A bundle elevator on the corn harvester saves much hard labor in loading the heavy bundles. (From New York State College of Agriculture, Cornell University.)

The suitability of various crops for silage is discussed in the following chapters. Corn and the sorghums are ideal silage crops. At the proper silage stage they contain enough sugar so that sufficient acid is produced in the silage fermentations to make silage of high quality. With these crops there is no need whatsoever of adding a preservative, such as molasses or mineral acid.

Especially in the northeastern states, the making of "grass silage," or hay-crop silage, has increased greatly in recent years. Grass silage is the term applied popularly to silage made from any uncured hay crop, no matter whether it is

or immature ear corn, sunflowers, beet tops, wet beet pulp, apple pomace, and potatoes.

Weeds and other waste vegetation may sometimes be advantageously ensiled. Cabbage, rape, and turnips make unsatisfactory silage, ill-smelling and watery.

428. Special methods necessary to insure good hay-crop silage.—Unless a special method is used in ensiling a hay crop, particularly a legume crop, the silage is apt to be of poor quality. On the other hand, very satisfactory silage can be made by the methods described later.

The chief reason why a special method is necessary in ensiling hay crops is that they contain a much smaller percentage of sugars than does corn or sorghum forage at the proper silage stage.[7] Sufficient acid may therefore not be produced in the silage to keep it from spoiling or from having a very strong, undesirable odor.

Legume forage, such as alfalfa or clover, is lower than grass forage in sugars. Also, legume forage is more alkaline in nature than corn or sorghum forage, and this alkalinity neutralizes some of the acid that is formed through the fermentation of what sugar there is in the crop.[8] In addition, legume forage tends to bind chemically and counteract acidity, because of its richness in protein.

Another reason why a special method is needed to make good hay-crop silage is that green legumes and grasses at the usual hay stages generally have less than 25 per cent of dry matter. Such forage is too watery to make high-quality silage unless a special method is used. Alfalfa or clover in early bloom or before bloom may have only 20 to 23 per cent dry matter or even less.

Many investigations have been conducted in recent years by experiment stations in this country to determine the best methods to use in making silage from hay crops. The most important results of these studies are summarized in the following articles.

429. Wilting the forage.—It has previously been pointed out that to make high-quality silage, hay crops should contain 30 to 35 per cent dry matter. If possible, the crop should therefore be allowed to wilt somewhat in the swath before it is ensiled, in order to bring the dry matter percentage up to this level. Wilting is impossible when a forage harvester is used which chops the forage as it is mowed. On a dry, sunny day an interval of 2 to 3 hours between mowing and loading will probably be enough for sufficient wilting. If the forage dries out too much, it will not pack well and it is apt to mold. Also, more of the carotene (vitamin A value) will be destroyed. In a very dry season, or with rather mature crops, wilting of the forage is not necessary.

One reason why wilting the forage improves "grass silage" is that it increases the amount of sugar in each pound of forage, due to the removal of part of the water. Pennsylvania studies also indicate that wilting such forage as alfalfa actually increases the percentage of sugar in the forage, on the dry basis.[9] If legumes or grasses are wilted to just the right extent, silage of good quality can usually be made from them without the addition of any preservative. However, it is difficult to get exactly the right amount of dry matter in the forage, and therefore many farmers prefer to use a preservative, even when the crop is wilted before it is ensiled.

If watery forage crops are not wilted, there is apt to be much leakage of juice from the silo, if the excess juice can get out. This not only wastes nutrients, but the juice is apt to be very foul-smelling as it decays. In addition, watery silage exerts such great pressure on the silo that the walls may give way. Such silage also has a destructive action on concrete.

Many farmers use the "squeeze test" to determine whether the forage has the proper dry matter content. A handful of the chopped forage is given a good hand squeeze with both hands. If moisture appears between the fingers, or if the material stays in a compact ball when pressure is released, it is too wet to ensile without a preservative.

If it expands gradually, the dry matter content is probably about right. On the other hand, if it crumbles and falls apart, it is too dry. The test does not work well with forage containing a high percentage of Ladino clover or with very coarse forage, such as sweet clover.

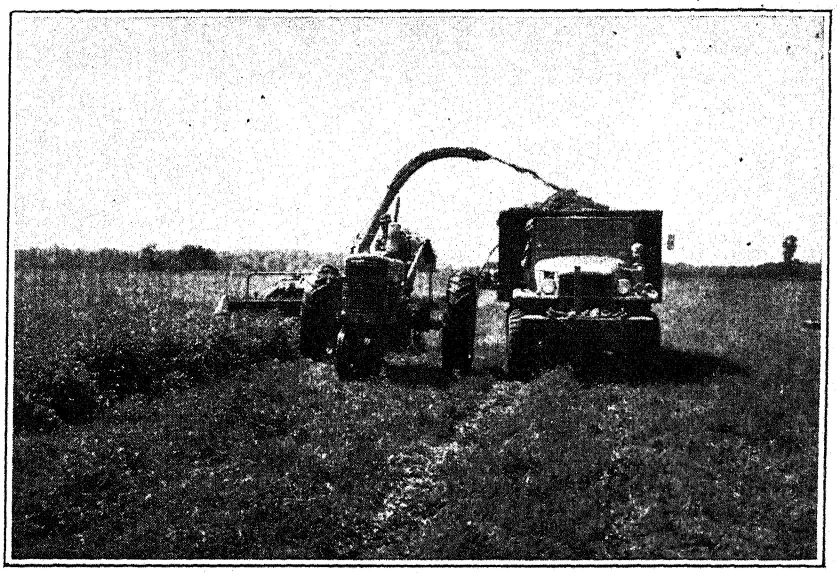
The moisture content of the forage can be determined by cutting up with shears a carefully taken sample and weighing it before and after drying in an oven at a low heat.[10] A home-made moisture tester for silage has been devised and also other relatively simple moisture testers.[11]

430. Addition of molasses.—The method used most widely in this country for improving hay-crop silage, or so-called "grass silage," is the addition of molasses as a preservative. This increases the sugar content so that enough acid is formed in the fermentations to preserve the silage properly.

The addition of molasses decidedly improves the quality of legume or grass silage that is too low in dry matter to make good silage otherwise. Even when the forage is wilted, molasses is apt to improve the quality and palatability of the silage, unless the dry matter content is just right and due care is taken in ensiling the forage. The carotene content of the silage also tends to be higher when molasses is added.

Most of the feeding value of the molasses that is added remains in the silage, because the sugar in the molasses is converted chiefly into lactic and acetic acids, which have food value. It is estimated that about 75 per cent of the nutritive value of the molasses remains in the silage. Cane molasses, beet molasses, corn molasses, citrus molasses, or wood sugar molasses can all be used for this purpose.

The amount of molasses needed per ton of green forage will range from 80 lbs. (7 gallons) for legumes in early bloom or before, to 40 lbs. for grasses or green cereals. The more immature the crop is, the larger is the amount of molasses advised. Some recommend 100 lbs. of molasses per ton for soybeans ensiled before the seed has developed much.



CUTTING A LEGUME-GRASS MIXTURE FOR SILAGE

The making of hay-crop silage, or so-called "grass silage," has increased greatly in recent years. This fine crop of mixed legumes and grass should make good silage. (From New York State College of Agriculture.)

If the silage cutter or blower is not equipped with a molasses pump, the molasses can be run into the blower or the silage cutter from a barrel on an elevated platform, through a hose or pipe with a valve for adjusting the rate of flow. In cool weather if the molasses is too thick to flow fast enough, it can be diluted with a little water.

431. Addition of ground grain or other dry feeds.—Experiments have shown that excellent silage can be made

from legumes or other hay crops when there is added as a preservative ground grain or certain other dry concentrates. One of the benefits from such an addition to forage low in dry matter is that it decidedly increases the percentage of dry matter.

For example, 150 lbs. of grain (about the usual amount added per ton of forage) contains over one-quarter as much dry matter as there is in a ton of green hay crop with 22 per cent dry matter. Adding the grain will raise the dry matter in the silage to more than 26 per cent.

The addition of ground grain also increases the palatability of the silage, because grain is so well liked by stock. Adding grain may also increase the amount of acid produced in the silage, as some acid may be formed from the starch in the grain. Probably at least 75 per cent of the feeding value of the grain is retained in the silage.

The following amounts of ground grain should be added per ton of green forage: For alfalfa, clovers, or lespedeza, 125 to 150 lbs.; for soybeans, 200 lbs.; for grass or cereal forage, 75 lbs.; and for mixed legumes and grasses, 100 to 125 lbs., depending on the proportion of legumes. If corn-and-cob meal is used instead of ground corn or other grain, the amount should be increased about one-quarter.

Good results have been secured when there has been added in making hay-crop silage similar amounts of dried citrus pulp, dried beet pulp, dried molasses-beet pulp, or brewers' dried grains.

Sometimes 300 to 400 lbs. of dry corn or sorghum fodder or stover, or else hay, are added to each ton of a watery hay crop as it is run through the silage cutter. Experiments have shown that it is doubtful whether this usually produces as good silage as is made when the hay crop is merely wilted to the proper degree.

432. Addition of mineral acid.—Another method is the addition of acid to the forage as it is ensiled. This acid, together with the acid formed through the fermentation of the sugar contained in the crop, produces sufficient acidity to make satisfactory silage. This method has been used but little by farmers in this country.

Sometimes phosphoric acid has been used as a preservative in making hay-crop silage. It does not have the strong corrosive effect of such acids as sulfuric acid or hydrochloric acid. Also, it increases the residual manurial value of the silage. Food-grade phosphoric acid should be used, as lower grades may contain injurious substances. The amount of liquid phosphoric acid generally recommended per ton of forage ranges from 16 lbs. (5 quarts) of 68-per-cent phosphoric acid (or 14 lbs. of 75-per-cent acid) for legumes to 9 lbs. of 68-per-cent phosphoric acid for grasses or cereals. About one-half of the cost of the phosphoric acid is returned in the increased fertility value of the manure resulting from feeding the silage.

The nutrients in a hay crop are well preserved by the phosphoric-acid method. However, in recent experiments the silage has been somewhat less palatable to stock than silage made with molasses or ground grain as the preservative. Also, when dairy cows have been fed large amounts of phosphoric-acid silage for a long period, they sometimes have not seemed to be as thrifty as when fed other silage.

In order to neutralize the considerable amount of mineral acid in phosphoric-acid silage, ground limestone or some other form of calcium carbonate should be fed with it.[12] For cattle, 2 ounces per head daily of ground limestone or a mixture of limestone and sodium bicarbonate are sufficient.

In the A.I.V. method, a mixture of hydrochloric acid and sulfuric acid is added to the forage. This patented method is employed to a considerable extent in northern Europe, where hay-crop silage is commonly made in pits or trenches, often without chopping. It has been used but little in the United States, because it has no special advantages, and the acids have a destructive action on clothing, the silo-filling machinery, and the silo wall.

433. Ensiling mixtures of legumes and other forage.—Good silage can be made from a mixture of legume forage, such as alfalfa or soybeans, with a suitable proportion of green corn or sorghum forage, which contains much more sugar. Since sorghum forage has more sugar than corn forage, less of it is needed. One ton of green sorghum to each 3 tons of alfalfa or soybeans should be sufficient, while it is best to have about equal weights of corn forage and legume forage.

434. Sodium bisulfite; sulfur dioxide.—A few years ago the use of sulfur dioxide was proposed to improve the quality of hay-crop silage, by decreasing the fermentations. At first, the method was used of injecting sulfur dioxide gas into the ensiled forage, from the cylinders in which it is shipped under great pressure, at points a few feet apart into each 2 or 3 foot layer of silage.[13] This method takes considerable time and the sulfur dioxide may not become uniformly distributed in the forage.

A much less troublesome way of adding sulfur dioxide is to add 8 lbs. of sodium bisulfite per ton to the forage as it is ensiled.[14] Sodium bisulfite (sodium metabisulfite) has been used for many years in the preservation of certain human foods.

The sodium bisulfite, which is a dry powder, can be applied to the chopped forage as it is ensiled by means of a special device, or by means of a fertilizer distributor, borrowed from a corn planter.

Several experiments have been conducted to compare this method, proposed by the Pennsylvania Station in 1952, with other methods of making hay-crop silage.[15] These studies have shown that the chief advantage of the method is that it usually improves the odor of the silage decidedly, due to a reduction in butyric acid and in putrefaction. Also, the addition of sodium bisulfite may increase the preservation of carotene, but all good hay-crop silage has an abundance to meet the needs of livestock.

In some experiments sodium bisulfite silage has been more palatable than other hay-crop silages, but in other trials it has been less palatable even than silage made with no preservative. While the results of the various experiments have differed considerably, the sodium bisulfite method does not apparently reduce the loss of dry matter appreciably, or improve the digestibility of the silage.

The most extensive feeding trials with sodium bisulfite silage yet reported are those by the New York (Cornell) Station.[16] During 2 seasons silage was made from mixed legumes and grasses (75 per cent legumes), cut when the legumes were in early bloom. The forage contained only about 20 per cent dry matter and was not wilted, as it was harvested with a field chopper. Each kind of silage tested was fed as the only roughage to dairy cows, with the usual amount of concentrate mixture.

In amount of silage eaten per head daily, in milk production per cow, in dry matter required per pound of milk, and in gain in live weight, the sodium bisulfite silage ranked slightly below silage made with no preservative or silage made with molasses. In warm weather the sodium bisulfite silage tended to spoil, after removal from the silo, sooner than the other silages. The only advantage of adding sodium bisulfite seemed to be the production of good-smelling silage, and a somewhat better preservation of carotene. However, the other silages had plenty of carotene.

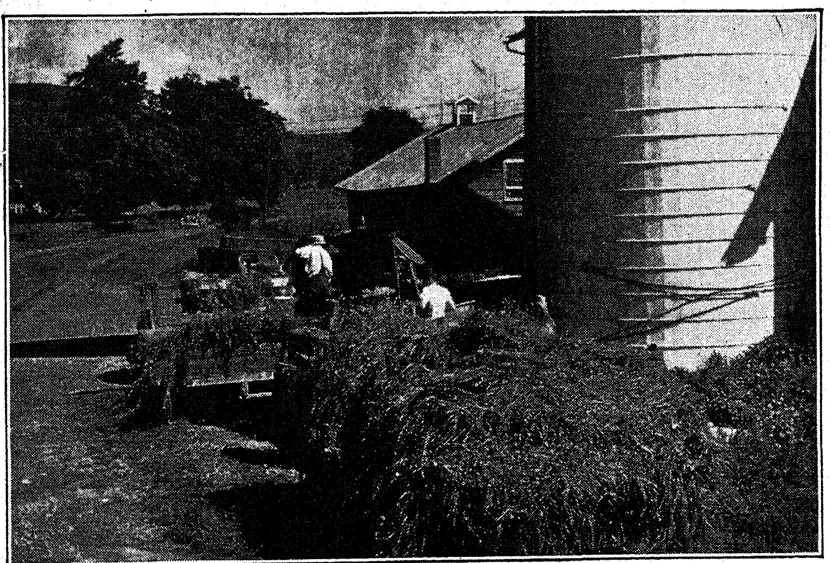
435. Other methods.—Sometimes dried whey or even undried whey is added in ensiling a hay crop. The results are apt to be inferior to those from using molasses, ground grain, or mineral acid, or from wilting the crop.

Silage made with the addition of a commercial mixture consisting chiefly of calcium formate and sodium nitrite was inferior to no preservative or sodium bisulfite silage in an Illinois trial, and to silage made from wilted forage in an experiment by the United States Department of Agriculture.[17]

Occasionally salt is added to the hay-crop forage, but it is very doubtful whether this produces any appreciable benefit.

Claims that lactic acid cultures improve the quality of silage have been proven false.[18] All green silage crops have an abundance of such bacteria. Methods of treating the ensiled forage with currents of electricity[19] or steaming it[20] to kill the bacteria have not proven advantageous.

In an Italian method grasses or legumes are dried to a dry matter content of 60 to 70 per cent before ensiling.[21] The silage is heavily weighted in a tower silo by means of a wooden cover and large stones, so as to force out most of the air and reduce the fermentations. Without such weighting, forage as dry as this would be apt to mold or even char.



MAKING A HAY CROP INTO SILAGE CONSERVES NUTRIENTS

The loss of nutrients is usually less when a hay crop is made into silage by a suitable method than when it is made into hay in the ordinary way. (From New York State College of Agriculture, Cornell University.)

436. Pros and cons of hay-crop silage.—Many experiments have been conducted in recent years to determine the feeding value of hay-crop silage, and especially to compare it with corn silage or with hay. These studies have shown that one of the chief advantages of hay-crop silage is that it can be made when the weather is so rainy that it is impossible to make good field-cured hay.

Part of the first cutting of legume or mixed legume-grass hay can be ensiled earlier than the usual stage for making hay, when the crop has a very high feeding value per ton of dry matter. A larger second crop of hay can then generally be obtained, which can be made into good hay, as the weather in late summer is usually more favorable for field curing.

Making part of the first cutting into silage early helps to distribute the labor of harvesting the hay crops, and it aids in controlling weeds.

By ensiling hay crops, good silage can readily be provided in regions where the climate is too cool or the growing season is too short for corn or the sorghums to thrive. Where fields are subject to severe erosion, growing hay crops for silage instead of corn or sorghum largely prevents erosion.

Double use can be made of a silo

when it is filled in the fall with corn or other silage for winter feeding, and then filled again early in the summer with first-cutting hay crop. This silage can be fed during the summer as a supplement to pasture when the pasturage becomes scanty.

It has been shown in the previous chapter that the total losses of dry matter and of nutrients are generally slightly less when a hay crop is ensiled by a good method than when it is made into field-cured hay, even in good weather. (398) The difference is great in the case of carotene. In rainy weather the loss of dry matter and of nutrients is much greater in field-cured hay than in silage.

Another advantage of hay-crop silage is that stock usually eat it with less wastage than in the case of hay of ordinary quality.

One of the disadvantages of hay-crop silage is that it often has a very penetrating and disagreeable odor, even when made by one of the special methods that have been described. This is more objectionable to humans than to livestock. Usually stock like hay-crop silage when they become used to it, but sometimes they will not consume as much as of corn silage. With hay-crop silage there may be more trouble in very cold weather from freezing next to the silo wall than with corn silage.

The cost of storing a hay crop as silage is often greater than the cost of making it into hay in good hay-making weather, because of the large amount of water that must be handled in the green crop. In general, there is little or no advantage in ensiling hay crops in a region where the climate is such that it is generally easy to make them into hay of good quality. It must always be remembered that good silage cannot be made from any crop that would not make satisfactory hay if it could be cured satisfactorily.

In ensiling hay crops, the forage should be cut fine, as it then packs quickly and closely, forcing out the air. For wilted or rather mature forage, the cutter should be set for the shortest cut available. An unwilted crop, high in water, need not be cut so fine, except towards the top of the silo.

When the wilting method is used in making hay-crop silage, the top few feet in the silo should not be wilted, for the wet, heavy forage will pack better and reduce surface spoilage. Also, it is best to add molasses or another preservative to the top portion.

A silo for hay-crop silage must be well built and strongly reinforced to withstand the great lateral pressure as the silage settles.

437. Nutrients in hay-crop silage.—The percentage of dry matter in hay-crop silage varies widely, depending on whether or not the crop was wilted before being ensiled and also on the stage of maturity. Separate averages are therefore given in Appendix Table I for wilted silage of various kinds and for unwilted silage, so far as sufficient data are available.

In general, hay-crop silage is appreciably lower in total digestible nutrients, and especially in net energy, than well-eared corn silage which has the same percentage of dry matter. This is because hay-crop silage lacks the large amount of grain that well-eared corn silage contains. Experiments have also shown that hay-crop silage is a little lower in total digestible nutrients, on the dry basis, than good hay made from the same crop.[22]

On the dry basis, hay-crop silage is similar in content of total digestible nutrients to immature corn silage or corn silage with only a few ears. Because of the lower content of total digestible nutrients and net energy in hay-crop silage, compared with well-eared corn silage, it may be necessary to feed high-producing animals a somewhat larger allowance of concentrates with hay-crop silage. This is especially apt to be the case with fattening cattle or lambs.

The difference in total digestible nutrients may be entirely or largely offset by the fact that most hay-crop silage is much higher in protein than corn or sorghum silage. Less protein supplement is therefore needed with hay-crop silage. Often, no protein supplement at all is re-

quired with hay-crop silage, while it would be necessary with corn or sorghum silage. This is an important point when protein supplements are decidedly more expensive than farm grain, but it is frequently overlooked.

Hay-crop silage of good quality is much richer in carotene than field-cured hay made from the same crop. (**196**, Appendix Table V) It also has much more carotene than corn or sorghum silage.

While field-cured hay usually supplies considerable vitamin D, hay-crop silage that has not been wilted has very little. This is because green forage crops have practically no vitamin D, but contain ergosterol, from which the vitamin is formed during field curing through the action of the ultra-violet light in the sunlight. (**201**, **204**) Hay-crop silage that has been wilted in the field may have sufficient vitamin D to protect calves against rickets when they have no other source of the vitamin.

Because hay-crop silage does not supply much vitamin D, it is not advisable to use it as the only roughage for cattle or sheep throughout the winter, unless they are exposed to considerable direct sunlight or are fed a vitamin D supplement.

438. Hay-crop silage for dairy cattle.—Hay-crop silage, or "grass silage," is used in this country much more extensively for dairy cows and heifers than for other classes of stock. A great number of experiments have therefore been conducted by our experiment stations to determine the value of hay-crop silage for dairy cattle and to find the best ways of using it.[23] From a study of the results of these many investigations, the following conclusions can be drawn:

When hay-crop silage is added to a ration of good hay and concentrates, the milk production of cows is usually increased slightly. This is because a good succulent feed tends to raise the milk yield somewhat. (**524**) Whether or not the increase will be marked will depend chiefly on the quality of the hay. If the hay is rather poor, there will be a decided benefit from the addition of silage to the ration.

Experiments have shown that hay-crop silage is generally worth more, per 100 lbs. of dry matter, than good hay made from the same crop. This is in spite of the fact, mentioned previously, that the content of total digestible nutrients in hay-crop silage is a trifle less, on the dry matter basis, than in good hay made from the same crop.

As has been stated previously, the losses of dry matter and of nutrients are generally a little less when a hay crop is made into good silage than when the crop is field-cured into hay. In rainy weather there is considerable difference in favor of silage.

In extensive experiments by the United States Department of Agriculture, in which both the losses of dry matter and nutrients and the actual feeding value of the forage were considered, wilted alfalfa silage produced 5 per cent more milk per acre than field-cured hay made in good weather. The value of the silage per acre was 31 per cent greater than that of field-cured hay which was damaged by rain.

The wilted silage had about the same feeding value per acre as barn-dried hay, ranking slightly above barn-dried hay made with unheated air and a trifle below barn-dried hay made with heated air.

These and other experiments show that about the same feeding value per acre for dairy cows is secured when a hay crop is made into silage by a good method as when it is barn-dried. The choice between the two methods should therefore depend on the relative cost and convenience on any particular farm.

In some experiments hay-crop silage has been fully equal in value per ton for milk production to well-eared corn silage containing the same percentage of dry matter. However, in other trials in which equal amounts of concentrates have been fed, there has been a tendency for the milk yield to be a trifle lower on hay-crop silage, or for the cows not to maintain their live weights quite so well. Such a tendency can be prevented by increasing the allowance of

concentrates somewhat, to make up for the lack of grain in hay-crop silage.

This advantage of well-eared corn silage may be off-set by the fact that legume or legume-grass silage is much richer in protein. Therefore, decidedly less protein is needed in the concentrate mixture than with corn or sorghum silage. Often dairymen do not fully take this difference into consideration when substituting hay-crop silage for corn or sorghum silage.

The high milk production which can be secured on home-grown feed by the use of silage, hay, and pasture rich in legumes is well shown by the results obtained by an Illinois dairyman.[24] His 21-cow herd averaged 525 lbs. of fat a year without the feeding of any purchased concentrate. A mixture of only ground corn and oats, with minerals, was fed at a moderate rate. The excellent production was due to the fact that in winter the cows were fed all the legume-grass silage (made with ground corn as a preservative) and all the excellent mixed hay they would clean up, and in summer they had good legume-grass pasture, with a little hay supplied in addition.

Hay-crop silage can be used as the only roughage for dairy cows or heifers, but the best results are usually secured when it is fed in combination with some hay. When cows are fed only hay-crop silage for roughage, they will generally not consume as much roughage, on the dry basis, as when they are fed both silage and hay. The only exception seems to be with hay-crop silage that is wilted so that it has a high content of dry matter. Such silage is, however, apt to mold unless great care is taken to cut the forage very fine when it is ensiled, and to tramp it well in the silo.

When hay-crop silage of the usual type is fed to dairy cows as the only roughage, it is generally necessary to feed more concentrates than usual. If this is not done, the cows are apt to drop in milk production or to lose body weight, because of a smaller intake of nutrients.

If there is a more abundant supply of hay-crop silage than there is of hay, the amount of hay can be reduced somewhat, with entirely satisfactory results. Dairy cows are ordinarily fed at least 1 lb. of hay daily per 100 lbs. live weight. However, good results are secured when only 5 to 7 lbs. of well-made hay are fed per head daily, along with all the silage the cows will eat and the usual amount of concentrates.

Hay-crop silage is an excellent supplement to pasture for dairy cows, being equal to good hay for this purpose in a Georgia experiment.[25] Feeding the silage to cows on pasture was not unduly laxative, and milk production and live weights were maintained as well as when hay was fed on pasture.

When part of the first cutting of hay is made into silage, excellent use can often be made of the silage for supplementing scanty pasture in midsummer. Then the silo can be filled again with corn or sorghum silage in the fall.

Because hay-crop silage usually has much more carotene than field-cured hay or than corn or sorghum silage, the vitamin A value of winter milk is increased decidedly when hay-crop silage is fed. Also, the milk, especially of Guernseys and Jerseys, is yellower in color, because of the greater carotene content.

If hay-crop silage is fed only after milking and in a well-ventilated stable, the strong odor it often has does not injure the flavor of milk or of dairy products. Indeed, the feeding of hay-crop silage under proper conditions may improve the flavor of milk and also reduce the tendency for oxidized flavor to develop in pasteurized milk. Care should always be taken not to leave any uneaten silage in the manger to spoil, and not to have piles of silage in the stable at milking time.

Hay-crop silage can be used for growing dairy heifers in the same manner as for dairy cows. It is shown in Chapter XXVII that the results of the experiments have differed greatly in which hay-crop silage has been compared with good hay for heifers. (1135) Often heifers will consume much less dry matter than normal, if fed hay-crop silage as the only roughage or with but a small

allowance of hay. They will then need a greater amount of concentrates to make good growth.

Hay-crop silage that has not been wilted in the field is usually too low in vitamin D to protect calves against rickets, when they have no exposure to sunlight. On the other hand, wilted silage may supply sufficient of the vitamin. (204)

439. Hay-crop silage for beef cattle.—In several experiments with fattening cattle fed a liberal amount of grain, hay-crop silage has been equal in value per ton to corn silage containing a similar percentage of dry matter.[26] On the other hand, when cattle are fattened chiefly on roughage, with only a small amount of concentrates, the lack of grain in hay-crop silage is a decided disadvantage.

Fattening cattle need considerable grain or other concentrates to make rapid gains and become well fattened. Therefore on a high-roughage ration it is generally necessary to feed a larger amount of concentrates with hay-crop silage than with well-eared corn silage, to produce as rapid gains and as good finish.

This disadvantage is partly offset by the fact that most hay-crop silage is considerably higher than corn silage in protein. Consequently, there may be no need to feed a protein supplement with hay-crop silage, even though a supplement is needed when corn silage is used.

In a recent Ohio trial yearling steers gained 2.0 lbs. a day on only corn silage supplemented with 1.5 lbs. of soybean oil meal per head daily.[27] To produce equal gains it was necessary to give steers fed hay-crop silage 8 lbs. of corn-and-cob meal a day. In this trial hay-crop silage was worth only 52 per cent as much per ton as corn silage.

In each of 4 Michigan experiments one lot of cattle was fattened on a ration of corn silage, legume or mixed hay, and protein supplement, with an average of only 1.6 lbs. corn grain per head daily in addition.[28] Another lot was fed hay-crop silage (largely alfalfa), with enough corn grain to produce gains equal to the first lot. This required 8.7 lbs. of corn per head daily. In these trials the hay-crop silage was worth 84 per cent as much a ton as the corn silage.

A third lot of cattle in each experiment was fed alfalfa hay and enough corn grain to produce gains equal to the first lot. This required about the same amount as for the cattle fed hay-crop silage. On the average, hay-crop silage was worth 58 per cent as much a ton as alfalfa hay.

In New York and West Virginia experiments satisfactory results were secured when beef cows were wintered on a limited amount of good hay plus either hay-crop silage or corn silage.[29] In the New York trials the hay-crop silage, on the dry-matter basis, was worth 80 per cent as much per ton as corn silage. In the West Virginia trials, where equal amounts of dry matter were fed, the cows gained slightly more on corn silage. In other West Virginia experiments beef cows gained a little more when fed both hay-crop silage and hay than when fed either hay or the silage alone.[30]

Experiments have shown that hay-crop silage usually has a much lower value for wintering beef calves than for beef cows. Beef calves make satisfactory gains when wintered on only good alfalfa or other legume hay, or else on corn or sorghum silage plus a small amount of protein supplement. However, if fed only hay-crop silage the gains are generally unsatisfactory, though such silage has plenty of protein.[31]

To produce good gains on hay-crop silage, it is necessary to feed the calves 2 to 3 lbs. or more of grain or other concentrates. In New York tests hay-crop silage was worth only 57 per cent as much per ton as corn silage, on equal dry matter basis, in comparison with 80 per cent as much for beef cows.[32] The difference was probably due to the fact that growing calves need a ration richer in net energy than do mature cows being wintered.

440. Hay-crop silage for sheep.—Hay-crop silage is a satisfactory substitute for corn silage or for hay in feeding sheep. It is not generally used as the only roughage, but is best fed in combination with hay. However, in Kentucky,

Michigan and Ohio experiments satisfactory results were secured when pregnant ewes and other sheep were wintered on hay-crop silage as the sole roughage.[33] Ewes thus fed will eat 10 to 12 lbs. of silage per head daily. On the average, hay-crop silage was worth about 40 per cent as much per ton as hay in feeding value.

Since hay-crop silage lacks the considerable amount of grain there is in well-eared corn silage, breeding ewes or fattening lambs may need more grain when hay-crop silage replaces corn silage. However, a protein supplement may be needed with corn silage and not with hay-crop silage, which usually has much more protein.

In South Dakota experiments fattening lambs made equal gains when fed rations of corn grain, protein supplement, a little hay, and either alfalfa silage or corn silage.[34] The alfalfa silage was worth slightly less per ton than the corn silage. Less satisfactory results were secured in New Mexico trials where alfalfa silage was used as the only roughage for fattening lambs.[35]

441. Hay-crop or grass silage for other stock.—Hay-crop silage is not commonly fed to horses, but it can be used in the same manner as corn silage. (**528**) Special care should be taken not to feed any spoiled silage to horses.

Legume silage can be used instead of legume hay as a vitamin A supplement for swine. However, it has but little vitamin D, unless it has been wilted in the field. It is therefore generally better to include good-quality, field-cured alfalfa or other legume hay in the winter rations for swine.

Grain can be saved by feeding brood sows hay-crop silage in winter, just as with legume hay.[36] However, in Minnesota tests feeding hay-crop silage to sows after farrowing tended to cause scours in the nursing pigs.[37]

Silage made from alfalfa, clover, or other legumes, or from immature grass is sometimes fed to hens or other poultry, instead of using alfalfa meal as a vitamin A supplement.[38] When rations of hens contain the usual amounts of alfalfa meal and other vitamin supplements, the addition of such silage does not generally cause any improvement. Feeding more than 3 lbs. of hay-crop silage daily per 100 hens may produce dark-colored or greenish yolks. After hens become accustomed to silage, they sometimes will eat as much as 10 to 15 lbs. daily per 100 birds. Chicks do not eat enough hay-crop silage to provide sufficient riboflavin.

For poultry, silage is occasionally made in barrels or steel drums. The forage must be well packed and a cover should be used, with a heavy weight on top. This method takes much labor per ton of silage.

II. Silos and Filling the Silo

442. Requisites of a good silo.—To preserve silage best, an above-ground silo should have the following characteristics:

1. *Air tight walls.* The walls must prevent the entrance of air and the doors must fit snugly. If air enters, molds will grow, spoiling the silage.

2. *Cylindrical shape.* In the early silos, which were rectangular, it was exceedingly difficult to pack the forage tightly enough in the corners to prevent spoilage. The cylindrical silo has no corners, the sides are strong and unyielding, and it provides the largest possible cubic capacity for a given amount of building material.

3. *Smooth, perpendicular, strong walls.* Unless the walls of the silo are smooth and perpendicular, cavities will form along the walls as the mass settles, and the adjacent silage will spoil. The walls must be strong and rigid, for while the silage is settling a great outward pressure is developed. This is considerably greater in the case of hay-crop silage than with corn silage.

4. *Depth.* It has been emphasized previously in this chapter that the percentage loss of nutrients by surface spoilage is much less in a deep silo than in a shallow one. (**426**)

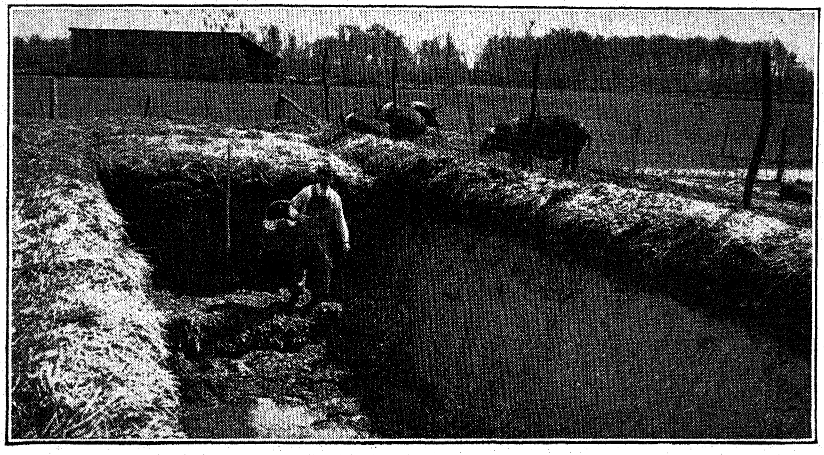
443. Types of silos.—Most above-ground silos in this country are constructed of wood, concrete staves, or glazed tile. Occasionally, silos are built

of solid concrete, brick, or galvanized sheet iron or steel. The choice between the various types of silos will depend on local conditions.

Especially in the drier regions, wide use has been made of trench silos during recent years. Where the soil is well drained, these provide a cheap and satisfactory means of ensiling crops. The losses of nutrients in trench silos are considerably greater than in the case of deep cylindrical silos, but this is more or less offset by the small cost. Occasionally, pit silos are used instead of trench silos.

On account of the shallowness, the trench silo and stacked the silage above this. Occasionally, instead of making a trench in the ground, earth is piled on each side so as to make an above-ground trench.

Temporary silos are occasionally made of slat or picket fencing, such as is used for snow fences. This is lined with a tough reinforced paper made for the purpose. "Snow-fence" silos are not well suited for ensiling hay crops, because heavy spoilage is apt to occur during summer in such silos.[39] They are more satisfactory with corn or sorghum silage.



A Trench Silo Provides Cheap Storage

Where the soil is well drained, a trench silo provides cheap storage for forage, but the losses of nutrients are higher than in deep cylindrical silos.

forage must be packed very thoroughly in a trench silo by driving a tractor or a team of horses back and forth over it, and when filling is completed the surface should be covered with wet straw or with straw and earth. Feeding is begun at one end, the silage being removed in vertical slices of a size which can be fed out in about two days.

Especially where the soil is not well enough drained for a trench silo, silage is sometimes made in above-ground large and long stacks, well compacted by running the trucks over the mass. Losses are apt to be higher than in a trench silo. Some farmers have made a shallow

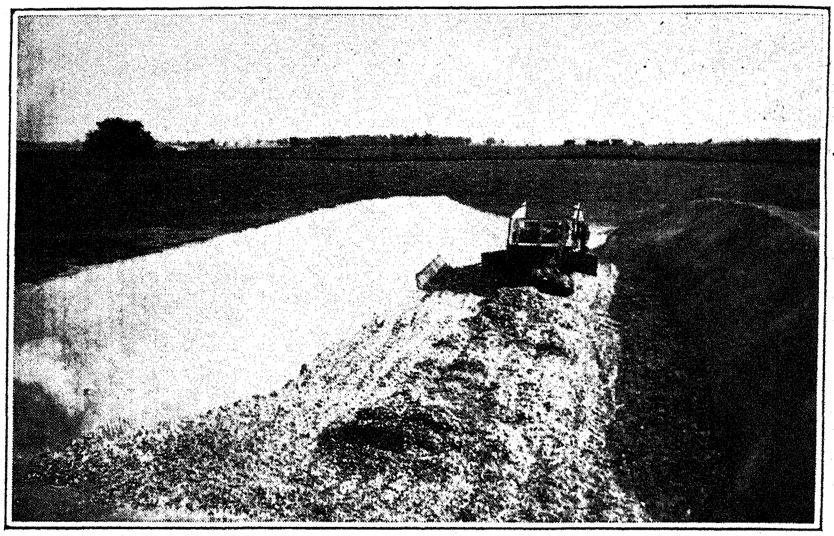
Gas-tight silos have been developed, which are made of glass-coated steel plates, and which have a mechanism at the bottom for removing the silage daily. In a test by the United States Department of Agriculture a comparison was made of grass silage in such a silo and in an ordinary tower silo.[40] Except for the top surface spoilage in the ordinary silo, there was no appreciable difference in the loss of dry matter or digestible nutrients in the two silos, or in the feeding value of the silage.

444. Filling the silo.—In ensiling forage it should be chopped fine by a silage cutter. Finely-chopped forage

packs more densely, it makes better silage, and the loss of nutrients is reduced to a minimum. Also, the silage can be removed much easier if the forage is chopped.

In this country silage cutters are generally set to cut the forage into pieces not over one-half inch long. For corn in the early-dent stage, a half-inch cut is satisfactory. For more mature corn and for hay-crop silage, a one-quarter inch cut is best, as the forage packs better.

is directed toward the center of the silo. The forage is then allowed to "cone up" as it falls. Sometimes a man levels it off after each load, but others do no levelling except toward the top of the silo. To avoid a large amount of spoilage at the top, it is important that for the last few feet the silage be levelled off and thoroughly tramped. Good results are secured by this method with corn or sorghum forage, if it contains sufficient water to pack well, but if it is a little



A LARGE ABOVE-GROUND TRENCH SILO

The cut forage is packed firmly by the trucks as the silo is filled. Such a trench silo can be used where the soil is not well enough drained for a regular trench silo.

dry, the silage is apt to be poor, especially near the wall. Thorough distributing and tramping is advisable with hay-crop silage.

The safest plan to insure good silage is to have a reliable man in the silo as it is filled, to distribute the forage uniformly by moving the flexible distributor pipe. In walking about, he will also help pack the forage. Toward the top of the silo the material should be tramped especially well near the wall, as the friction with the wall retards settling. Some advise keeping the center higher than the outside while filling the upper part of the silo, believing that this lessens the tendency of the silage to draw away from the wall as it settles.

To save labor, the plan is sometimes used of tying the distributor pipe so it

No matter what method is followed, if the forage is too dry to pack well when it is ensiled, water should be added. This may be done by running it into the blower-fan case or into the blower pipe just above the blower. If the water is under sufficient pressure, it may be allowed to run into the flexible distributor pipe in the silo, or the man who tramps the forage can carry the hose and wet the forage as he packs it.

The forage will settle considerably

after the silo is filled, and more may then be put in, any spoiled surface material being first removed. If feeding is not to begin immediately, the surface should be wet down thoroughly and tramped well several times the first week, when the rotting forage on top will form a layer that protects the rest. To lessen the waste, it is well to remove the ears from the last few loads of corn forage and to cover the top with a foot or so of cheap refuse, such as straw or weeds thoroughly soaked with water. Sometimes oats are sown on the surface. On growing, the roots form a dense mat which aids in keeping out the air.

The loss at the surface can be reduced to a minimum if the forage is covered (after it is levelled, thoroughly wet down, and well tramped) with cheap roll-roofing, the joints being lapped about 4 inches and the ends turned up against the side wall 4 or 5 inches. Then the roofing is covered with a few inches of silage, wet straw, sawdust, or other material. Heavy, strong wrapping paper, treated with lubricating oil, can be used in place of roll-roofing. Silo seals, made of plastic or rubberized fabric, have also been developed for reducing the surface spoilage.

If desired, feeding the silage can start immediately after the forage is ensiled. When feeding starts later, any spoiled material should always be removed from the top of the silage and put where stock cannot eat it.

445. Danger from carbon dioxide, or nitrogen dioxide.—On going into a silo after an intermission in filling or for a few days after filling, one should always guard against danger from carbon dioxide. This gas, which is heavier than air, may accumulate near the surface of the silage so that there will not be enough oxygen in the air for life. If a lighted lantern or candle lowered into the silo goes out, it is unsafe for one to enter. Opening a door near the surface of the silage will allow the carbon dioxide to escape. Before entering, agitate the air by operating the blower for a few minutes or by swinging a blanket vigorously.

Very rarely, poisonous yellow nitrogen dioxide gas is formed in silage soon after filling, apparently being produced from nitrates in the forage.[41] The gas is heavier than air and may accumulate near the surface of the silage or in the silo chute. Operating the blower for a few minutes before entering the silo will drive out any of this gas as well as carbon dioxide.

446. Weight of silage and capacities of silos.—Several investigations have been conducted to determine the weight of corn silage per cubic foot at various depths in cylindrical silos and the capacities of silos of various sizes, including studies by the United States Department of Agriculture and by the Kansas, Minnesota, Missouri, Nebraska and Wisconsin Stations.[42] These experiments show that silage is much more compact and heavier as the depth from the surface increases. The weight per cubic foot at any depth will vary considerably, depending especially on the percentage of water in the crop when ensiled and the amount of grain in it.

The experiments by the United States Department of Agriculture were with well-eared corn forage, ensiled at the early dent stage and having about the average percentage of water for well-eared corn silage. In these studies the average weight of a cubic foot of corn silage at the surface foot was 17.7 lbs.; at a depth of 5 feet, 39.8 lbs.; at 10 feet, 47.1 lbs.; at 15 feet, 50.5 lbs.; at 20 feet, 52.4 lbs.; at 25 feet, 53.7 lbs.; at 30 feet, 54.4 lbs.; and at 35 feet, 54.8 lbs.

The average weight of the silage for the whole depth was 31.6 lbs. per cubic foot for the first 5 feet, 38.1 lbs. for a depth of 10 feet, 41.8 lbs. for a depth of 15 feet, 44.3 lbs. for a depth of 20 feet, 46.1 lbs. for a depth of 25 feet, 47.4 lbs. for a depth of 30 feet, and 48.5 lbs. for a depth of 35 feet.

The following table shows the estimated capacity of silos of various sizes, according to these investigations, for well-eared corn silage ensiled in the early dent stage, cut in one-quarter inch lengths, well-tramped during filling of the silo, and with the silo refilled once

after settling for one day. The depth indicated is the actual depth of the settled silage, and not the height of the silo.

For corn silage differing from this type, the following changes should be made from the capacities shown in the table:

1. If the corn is well eared but immature, add 5 per cent to the number of tons shown. If it has only a fair number of ears, deduct 5 per cent, and if it has few ears or none, deduct 10 per cent.

2. If the corn grain is almost fully dented, deduct 5 to 10 per cent.

3. If the corn grain is fully dented and hard, deduct 15 to 20 per cent.

4. If the corn is cut in 5/8 to 3/4 inch lengths or longer, deduct 5 per cent.

The capacity of a silo for sorghum silage containing a good proportion of grain is about the same as for corn silage. Hay-crop silage is heavier than corn silage that contains the same percentage of dry matter. On the other hand, if the hay crop is wilted before ensiling, so that the percentage of dry matter is 30 per cent or more, the silage may be no heavier than corn silage. Sunflower silage is much heavier than corn silage.

Hay-crop silage has been found to exert a much greater lateral pressure on the silo wall during settling than does corn silage having the same moisture content. Silos for hay-crop silage therefore need additional reinforcing to withstand this pressure. This is also the case with sunflower silage.

447. Estimating the amount of silage in a silo.—To estimate the amount of silage remaining in a silo after part has been fed out, find the actual depth left and estimate the original total depth of silage after settling. Then compute the amount as follows: Let us suppose that 10 feet of silage are left in a silo having a diameter of 14 feet, and that after settling, the entire depth of silage was about 28 feet before feeding started.

From the table we find that at first the silo contained 101 tons. The first 18 feet of silage, which were fed out, contained about 60 tons, according to the table. The difference, or 41 tons, is the approximate weight of the silage left.

Tons of settled corn silage in cylindrical silos

448. Proper size of silo.—The diameter of the silo should depend on the number and kind of animals to be fed from it, and its height on the length of the feeding period. The silo should be of such diameter that in the cooler part of the year at least 1.5 inches, and preferably 2 inches, of silage will be removed from the entire surface daily to prevent spoilage. When silage is used for summer feeding, somewhat more should be removed daily.

The size of silo required may be computed from the length of the feeding period and the amount required

daily for the different kinds of stock, as shown previously in this chapter. Knowing the number of animals of each kind to be fed, the entire amount of silage which will be consumed daily may be ascertained. The maximum diameter which the silo should have may then be determined from the following:

Two inches in depth of ordinary corn silage average about 7.9 lbs. per surface square foot in a silo filled to a depth of 30 feet. To use 2 inches daily from the surface, approximately the following amounts must be fed from silos of various diameters: Diameter 10 feet, 620 lbs. silage; 12 feet, 895 lbs.; 14 feet, 1,215 lbs.; 16 feet, 1,590 lbs.; 18 feet, 2,010 lbs.; and 20 feet, 2,480 lbs.

When the maximum diameter which the silo should have has thus been determined, the total amount of silage required for the desired feeding period may be computed, and the dimensions for a silo of this capacity found by referring to the table given previously. It should be borne in mind that silage in a relatively deep silo keeps better than in a shallow one, as has been pointed out before. Also, when a silo is more than 18 or 20 feet in diameter, more labor is required in carrying the silage to the silo door as it is removed for feeding.

QUESTIONS

1. State 8 advantages of silage for livestock feeding.
2. Discuss the use and value of silage for dairy cattle, beef cattle, and sheep.
3. Under your local conditions should a dairy farmer raise silage for his cows, or should he use hay as the only roughage?
4. Describe in detail the changes that occur when a green crop is ensiled.
5. Discuss the efficiency with which nutrients are preserved in silage, stating the kinds of losses that occur and the approximate percentage of dry matter that is lost.
6. What characteristics should a good silage crop have?
7. Discuss the suitability of the following crops for silage: Corn, the sorghums, the small grains, alfalfa.
8. What special methods are used to produce better silage from hay crops? Describe 5 methods and state the quality of silage produced by each.
9. Discuss the advantages and disadvantages of hay-crop silage in comparison with corn silage and with hay.
10. Compare the content of hay-crop silage and corn silage in total digestible nutrients, net energy, protein, and carotene.
11. What is the relative vitamin D content of hay-crop silage and of field-cured hay?
12. Discuss the value of hay-crop silage for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) swine; (e) poultry.
13. State four requisites of a good silo.
14. State the advantages and disadvantages of trench silos.
15. Discuss the various methods of filling a silo with corn forage. Under what conditions might you allow the forage to "cone up" in the silo?
16. How can surface spoilage of silage be lessened?
17. How can you determine approximately how much silage is left in a silo after part of it has been fed out?

CHAPTER XVI

LEGUMES FOR FORAGE

I. Superiority of Legume Forage

449. Advantages of legume forage. —Legume roughages occupy a place of particular importance in the feeding of livestock, because of the several superiorities they have over all other forage crops. They excel in the following respects:

1. They lead in yield of palatable hay per acre. In nearly every livestock section of the United States some kind of legume will produce a greater yield per acre than other common hay crops. Moreover, this hay is so much more palatable than grass hay of the usual quality, that stock will eat larger amounts of it and thus get a larger part of their nourishment from this cheap source.

2. They are the richest in protein of all common forages. Therefore their use greatly reduces the amount of protein supplement needed to balance a ration. Indeed, merely good legume hay and farm grain make a well-balanced ration for some classes of stock.

3. Their protein helps correct the deficiencies in the proteins of the cereal grains. This is well shown by the fact that pigs fed only corn on alfalfa pasture will make fairly satisfactory gains, though they will do still better when a small amount of high-quality protein supplement is fed in addition.

For dairy cows, beef cattle, sheep, and horses, protein of entirely satisfactory quality is always assured whenever good legume forage forms any considerable part of the roughage.

4. Legume forages are the highest in calcium among all farm-grown feeds. If dairy cattle, beef cattle, sheep, or horses get plenty of good legume forage, there is no need to add a calcium supplement to the ration.

Legume roughages are not rich in phosphorus, containing less than do the cereal grains. However, their phosphorus content is generally a little higher than that of forage from corn, the sorghums, or the grasses.

5. Legume forage excels in vitamin A value. It has been pointed out in Chapter VII that well-cured legume hay has much more carotene, and consequently is much higher in vitamin A value, than is hay from the grasses or other dry forage. Legume silage is even richer in vitamin A value. During the barn-feeding season stock will generally have an abundance of vitamin A if good legume or mixed legume-grass hay or silage forms a considerable part of their roughage.

6. Field-cured legume hay is rich in vitamin D. Good-quality, field-cured legume hay is the richest source of vitamin D among common feeds. Dairy cows, beef cattle, sheep, and horses will be plentifully supplied with this vitamin when fed a reasonable amount of such hay, or of good field-cured mixed legume-and-grass hay. Only 5 per cent of field-cured legume hay in the ration will generally furnish enough vitamin D for pigs in winter.

7. Legume forage is rich in other vitamins. Plenty of good legume hay will usually supply ample amounts of the other vitamins needed by livestock, except in the case of poultry, which have especially high requirements for riboflavin and certain other B-complex vitamins.

8. Legumes increase the yield and protein content of grasses. Such legumes as alfalfa and the clovers increase the yield and protein content of the grasses when grown in combination with them. For pasture or for hay, a combination of grasses and legumes is therefore usu-

ally far preferable to any mixture of grasses alone, without legumes.

In Ohio experiments over several years a combination of timothy with red clover, alsike clover, or alfalfa yielded over 40 per cent more hay than timothy alone. Also, the percentage of protein in timothy or orchard grass (not including the legumes) was 44 to 50 per cent higher when grown with alfalfa than when the grass was grown alone.[1]

This beneficial effect of legumes upon the composition of grasses is probably due, at least in most part, to the nitrogen furnished to the soil when the nitrogen-bearing nodules on the legume roots are shed and decay.

9. *Legumes are highly important in maintaining soil fertility*. Through the action of the legume bacteria in the nodules on their roots, legumes use in their growth free nitrogen gas from the air. It must be kept in mind that they build up the nitrogen content of the soil only when the proper nodule-forming bacteria are present. Where these are lacking, it is essential that the soil be inoculated.

The legume bacteria are so effective in using nitrogen from the air that the nitrogen content of the soil may be increased even when such a legume hay crop as alfalfa or red clover is grown and all the hay removed, only the stubble and roots being returned to the soil.[2] On the other hand, when soybeans, which have a much less extensive root system, are grown for hay, without returning the manure, there may be a slight loss of nitrogen from the soil.

Not only do legume crops aid in maintaining the nitrogen supply in the soil, but also they increase the yield of succeeding crops by rendering the soil nitrogen more active and available and by producing other benefits. Thus, deep-rooted legumes, such as alfalfa and sweet clover, penetrate and open up soil layers below the plow line. The roots furnish organic matter to keep the soil particles aggregated and porous, thus improving soil structure.

The beneficial effects do not continue for many years after the growth of the legume crop. It is therefore advantageous from this standpoint, as well as for the maintenance of the nitrogen supply of the soil, to grow the legumes chiefly in regular crop rotations, instead of growing such a crop as alfalfa for a long time on the same field.

II. Alfalfa

450. Importance of alfalfa.—Over one-third of all the tame hay produced in the United States is now alfalfa (*Medicago sativa*). Alfalfa has come to occupy this leading position because it out-yields other hay crops and also because of its palatability, its richness in protein, and its high content of calcium and of vitamins. In addition to the importance of alfalfa for hay, alfalfa and alfalfa-grass mixtures are widely used for pasture and for silage. Because of the excellence of alfalfa hay and other alfalfa forage, they are commonly taken as the standards with which other forage crops are compared.

While alfalfa was at first raised chiefly in the western states, it is now grown in most areas of the United States where the soil is well-drained and not so acid as to make the cost of liming prohibitive. The North Central States now lead in acreage of alfalfa, though California is first in tonnage of alfalfa hay, because of the high yields secured under irrigation.

The reasons for the popularity of alfalfa hay are shown in the following table. This shows the average yield of nutrients per acre throughout the United States from alfalfa hay, from clover-and-timothy hay, and from corn silage.

Average yields of nutrients from alfalfa hay and other crops

	Yield per acre	Dry matter	Digestible protein	Total digestible nutrients
	Tons	Lbs.	Lbs.	Lbs.
Alfalfa hay	2.20	3,982	453	2,231
Clover-and-timothy-hay	1.41	2,484	132	1,438
Corn for silage	8.00	4,416	192	2,928

This table, computed from the average yields for the whole country, shows that alfalfa produces a much larger yield of hay and of dry matter

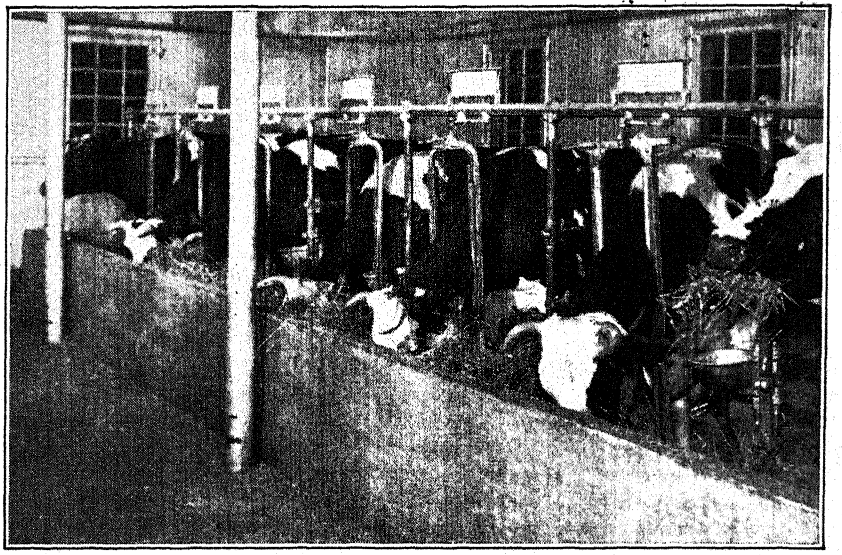
per acre than does clover and timothy. It is slightly excelled in yield of dry matter by corn grown for silage.

Alfalfa hay provides over three times as much digestible protein per acre as clover-and-timothy hay and 2.4 times as much as corn grown for silage. It furnishes much more total digestible nutrients per acre than does clover-and-timothy hay, and is excelled only by corn silage. In addition, alfalfa hay is much richer in calcium and also higher in carotene and other vitamins than are these other crops.

Considerably larger yields of alfalfa hay are secured under favorable conditions than shown in the table. Even in the eastern states, yields of 3 to 4 tons per acre during the season are not uncommon. In the West very heavy yields are often secured under irrigation. In the hot irrigated districts of the Southwest, 8 or even more cuttings are sometimes made in a year. Where both soil and climate are suitable, alfalfa returns good crops for many years without reseeding. When high temperature is combined with a humid climate, alfalfa generally fails unless the soil is unusually favorable.

Because alfalfa sends its roots deep into the subsoil on well-drained land, it is able to draw moisture from a great depth of soil. In a semi-arid climate this may bring about a decided depletion in the moisture of the subsoil, for the alfalfa can draw upon water which has been stored there over a long period. This depletion of subsoil moisture is one of the chief reasons why alfalfa often fails to thrive in such dry districts when seeded on land which has been in alfalfa several years. The very efficiency of the crop in obtaining water thus proves its undoing on that particular field. This probably has been the chief cause of the decrease in alfalfa acreage in certain western states during recent years.

Where alfalfa thrives best, it will produce a larger yield when seeded alone than when sown with a grass. In other areas, as is pointed out later in this chapter, the stand lasts longer and



LEGUME HAY IS UNEXCELLED AS ROUGHAGE

Legume hay and other legume forages are unexcelled, because of their several superiorities over other forages. Dairymen are fortunate who have an abundance of well-cured legume hay for their cows.

a larger yield is secured over a period of years when alfalfa is seeded in combination with a suitable grass, such as timothy or bromegrass. (469)

451. Varieties and types of alfalfa.—The *variegated alfalfas* are of much importance in the northernmost states and in Canada, as they are much more winter-hardy than common alfalfa. These varieties, which have various-colored and variegated blossoms, are hybrids between ordinary alfalfa and the yellow-flowered or Siberian alfalfa (*Medicago falcata*). To this class belong the well-known Grimm, Cossack, Ontario-Variegated, Baltic, Ladak, Hardigan, Ranger, Atlantic, and Narragansett varieties, and the new Vernal alfalfa.

Turkestan alfalfa is indistinguishable from common alfalfa in growth. It is somewhat hardier but usually yields less hay. *Peruvian alfalfa* is a rapidly-growing, non-hardy type, which is particularly well adapted to the southernmost alfalfa districts. Recently, creeping or pasture-type alfalfas have been produced, which spread by underground rootstalks and persist longer in pastures.

Varieties, such as Ranger, Buffalo, and Vernal, have been developed which are very resistant to bacterial wilt disease, and other varieties have been produced for certain areas, which are resistant to other diseases or to nematodes.

Which is the best variety for any area will depend entirely on the local conditions. Any person in doubt as to the variety to use should secure advice from his state experiment station, agricultural college, or county agent. The value of any variety will depend primarily on how it thrives in a given locality and on its yield. The value per ton of the forage from different varieties does not differ appreciably, so far as is known.

LEGUMES CAN USE NITROGEN OF AIR ONLY WHEN INOCULATED

When the nitrogen-fixing bacteria or germs are lacking, it is essential that the soil be inoculated to secure maximum crops. At left, are soybeans on sandy soil which were inoculated with the proper bacteria; at right, soybeans which were not inoculated. (From Wisconsin Station.)

452. Composition and value of alfalfa hay.—Alfalfa hay possesses to a high degree the nutritive advantages common to legume forages, which have been emphasized earlier in this chapter. (449) It has an average of 15.3 per cent protein, in comparison with 12.0 per cent for red clover, and the protein in alfalfa is more digestible. As a result, average alfalfa hay furnishes 10.9 lbs. digestible protein per 100 lbs., against 7.2 lbs. for clover.

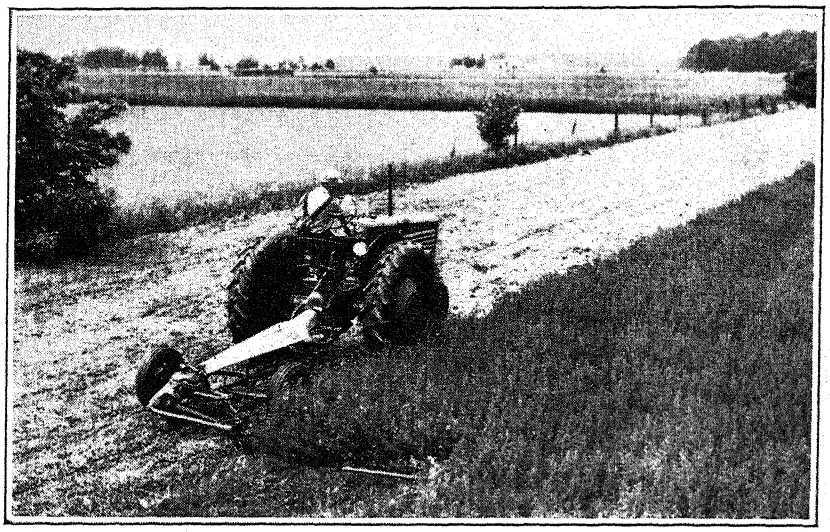
There is therefore a decided differ-

ence in the amount of protein supplement needed to balance a ration when stock are fed alfalfa hay in place of clover hay. Indeed, a supplement may not be required with alfalfa, while it may be needed with clover. The protein content of alfalfa hay varies considerably, even in hay harvested at the same stage of maturity and well cured. Occasionally it will contain no more protein than clover hay.

The fact that the protein of alfalfa helps to correct the deficiencies of the proteins of the cereal grains has been pointed out previously. (**126**)

Alfalfa hay supplies practically as much total digestible nutrients as does red clover hay, and is appreciably higher than timothy hay. In actual feeding experiments with dairy cows, beef cattle, and sheep alfalfa hay has always been equal or even superior to hay from the grasses in productive value, even when the lack of protein in grass hay was corrected by adding protein supplement.

However, in certain net energy investigations alfalfa hay has had a slightly lower net energy value than clover hay and a decidedly lower value than timothy hay.[3] This lower net energy value of alfalfa hay apparently results from a stimulating effect on body metabolism and heat production, perhaps caused by hormones present in alfalfa. (**54**) This stimulating effect on metabolism produced by hay from alfalfa and other legumes (which stimulation reduces its net energy value) is probably one of the reasons why such excellent production is secured when dairy cows and other stock are fed plenty of good legume hay.



ALFALFA IS OUR MOST IMPORTANT HAY CROP

A fine field of alfalfa. Because of the merits of alfalfa for hay, it has become the most important hay crop in the United States.

Because good alfalfa hay has been proven to be fully equal to first-class timothy hay in productive value in the practical feeding of livestock, the author has rated average alfalfa hay equal to excellent timothy hay in the estimated net energy values given in Appendix Table II.

Alfalfa hay is exceptionally rich in calcium, having an average of 1.47 per cent. This high calcium content is of especial importance for dairy cows, breeding stock, and young growing animals. Alfalfa hay has only a fair phosphorus content, averaging 0.24 per cent.

On phosphorus-deficient soils, it may be very low in phosphorus content.

Alfalfa hay of good quality has a high vitamin A value, because of its richness in carotene. For this reason, alfalfa meal, especially dehydrated alfalfa, is widely used to supply carotene and other vitamins in rations for poultry and swine. As has been shown earlier, the carotene content will vary widely, depending on the stage of maturity at which the hay was cut, on how well it was cured, and on how much carotene has been lost during storage. (**195–196**) Generally, leafy hay which has considerable green color will be good to high in carotene content.

Field-cured alfalfa hay is a good source of vitamin D for all stock except poultry. The form of vitamin D in alfalfa and other field-cured hays is not well utilized by poultry. Also, their requirements for the vitamin are so high that they need special vitamin D supplements, even when alfalfa products are included in their rations.

Good alfalfa hay is quite rich in riboflavin and in niacin. In addition, it has other vitamins that may be lacking in rations for animals which get no fresh green feed. (**222**)

Alfalfa is also a good source of vitamin K. (**225**) Even 1 to 2 per cent of good-quality alfalfa meal in the ration usually furnishes sufficient of this vitamin for poultry.

In this country, where yellow skin is preferred in market poultry, the xanthophyll in alfalfa meal helps to produce it. (**14**)

453. Differences in composition and value of alfalfa hay.—Alfalfa hay like all other kinds of hay, varies widely in value, depending, first of all, on how it was cured. (Chapter XIV) Hay of a good green color, cured without rain and with little shattering of leaves, has the highest feeding value. Since the leaves contain twice as high a percentage of protein as the stems, a considerable loss of leaves in hay-making not only decreases the yield of hay but also decidedly lowers the value per ton. Except from the vitamin standpoint, hay which is of good quality but not bright green in color may be about as valuable as green-colored hay, if it is as leafy and has not been leached by rain.

With hay cured equally well, the chief factor affecting the composition is the stage of maturity at which it is cut. The earlier the hay is cut, the higher it will be in protein and vitamins, the lower it will be in fiber, and the greater will be the digestibility. (Appendix Table I.) In general, alfalfa hay cut reasonably early (when from one-tenth to one-half in bloom) is best for dairy cows, beef cattle, sheep, and swine. That cut very early is preferred for poultry and rabbits. Hay cut in full bloom is best for horses, as early-cut hay may be too laxative. Hay cut too early may also cause scours in young calves.

When alfalfa hay is fed to dairy cows in the usual rations, along with a reasonable allowance of concentrates, there is not apparently much difference in the value per ton of hay cut extremely early and that cut in early bloom. For example, in extensive Arizona tests, there was no difference in the milk or fat production when cows were fed alfalfa hay cut at the bud stage in comparison with hay cut when one-third in bloom.[4] The bud-stage hay was slightly more palatable, and the cows ate a little more of it. To offset this, a trifle more of the concentrate mixture was fed with the one-third-bloom hay.

When alfalfa hay is fed to dairy cows as the only feed, as is sometimes done in certain sections of the West, hay cut very early will have an appreciably higher value than later-cut hay. In 3 Montana trials the milk production was 14 per cent higher when cows were thus fed alfalfa hay cut at the beginning of bloom, than when they were fed hay cut at the half-bloom stage.[5] The milk yield on hay cut at full bloom was 8 per cent below the yield on the hay cut at half bloom. Similarly, in Kansas tests beef steers fed only alfalfa hay cut at the bud stage made 18 per cent more gain per ton of hay than when fed hay cut when one-tenth in bloom.[6]

After the full-bloom stage, the value

of alfalfa hay falls decidedly. Such late-cut hay is less palatable and considerably lower in digestible nutrients. In the Kansas tests with beef steers, hay cut when one-tenth in bloom produced twice as much gain per ton as hay cut in the seed stage.

In trials by the United States Department of Agriculture dairy heifers were fed U.S. No. 1 or 2 alfalfa hay, containing 26 to 30 per cent fiber, as the sole ration, in comparison with poor alfalfa having 37 to 38 per cent fiber.[7] The heifers fed the good hay gained 28 per cent more and required 12 per cent less hay per pound of gain.

The relative value of the different cuttings of alfalfa hay will depend on climatic conditions. In the corn belt and eastward the first cutting is commonly coarser and less leafy than the later cuttings and therefore is of somewhat lower value, when the different cuttings are equally well cured. Also, the weather is often less favorable for curing the first crop. On the other hand, in some of the western irrigated districts, the first cutting is more leafy and finer stemmed than some of the later cuttings.

In general, fine-stemmed, leafy hay is worth more than coarser, stemmier hay. The difference in value is greatest for poultry, swine, and sheep, and is less for dairy cows or beef cattle which are fed concentrates in addition to the hay. In many districts there is a decided prejudice among stockmen in favor of a certain cutting of alfalfa hay, though the actual difference in value of the various cuttings may be much less than the difference in market price.[8]

Alfalfa hay badly damaged by rain, stemmy hay that has lost most of the leaves, or hay otherwise of poor quality has a much lower value than hay of good quality.[9] Stock will eat much less of such poor hay, and the nutritive value per pound is decidedly less.

Occasionally, cattle or sheep fed leafy, good-quality alfalfa hay as the only roughage tend to bloat. Such trouble may usually be prevented by feeding some non-legume roughage, such as corn or sorghum silage, along with the alfalfa.

The use of alfalfa straw or chaff is discussed later. (513)

454. Stage to cut alfalfa.—In deciding when to cut alfalfa for hay, one must consider not only the quality of the hay but also the effect upon the length of life of the stand. Extensive experiments have shown that, except perhaps where the conditions are most favorable to alfalfa, repeated cutting of a field before early bloom will weaken the plants and shorten their life. This is due to a depletion of reserve food in the alfalfa roots, brought about by the early and frequent cutting. These reserves are built up in the roots during the blossoming period and later.

Cutting a vigorous stand occasionally as early as the bud stage will not usually produce any noticeable injury, but the same field should not be cut early repeatedly. The same area should not be cut first each year, and it is wise to delay cutting of a new seeding until after the older stands have been cut.

In the humid districts, the first growth of alfalfa in the spring is generally coarser and stemmier than later cuttings. Cutting such rank growth reasonably early makes much better-quality hay than if it is cut when in full bloom. When leafhopper infestation is severe, cutting the crop at a particular time may aid in preventing damage. If alfalfa has been injured by severe winter weather, cutting it at the full-bloom stage the following spring will aid it to recover.

Where the winters are severe, the stand is maintained better if the alfalfa is not cut for hay in the fall or grazed closely, but a growth 6 inches or more in height is left for winter protection. When it is desired to cut alfalfa or to graze it in the fall, the stand is injured less if this is delayed until late October, by which time the fall growth will have been made and the storage of nutrients in the roots will have taken place.

Since the best practice will differ considerably in the various sections of the country, any person in doubt as to the best time to cut the crop should consult his agricultural college, experiment station, or county agent.

455. Alfalfa meal; alfalfa pellets.—More than one million tons a year of alfalfa meal are now produced commercially in this country for use in livestock rations, chiefly as a vitamin supplement. Except in certain western alfalfa districts where the climate is especially favorable for making high-quality field-cured hay, the alfalfa is dehydrated for this purpose.

Alfalfa meal is commonly used as a vitamin supplement in commercial poultry mashes, and it is also widely used to furnish vitamin A in formula feeds (commercial mixed feeds) for swine, dairy calves, and such animals as rabbits. It is likewise a common ingredient in formula horse and mule feeds.

The use of alfalfa meal and of alfalfa hay as a vitamin supplement for the various classes of stock is discussed in Part III. Information is given concerning the nutritive and feeding value of dehydrated hay in general in Chapter XIV. (**416–420**)

Alfalfa meal is the product obtained by grinding entire alfalfa hay without the addition of any alfalfa stems, alfalfa straw, or foreign material, or the removal of any of the leafy portion. It should be made from leafy hay of good quality, and the fiber content should not be higher than about 29 to 30 per cent, for the average fiber content of alfalfa hay is only 28.6 per cent. A higher percentage of fiber shows that the meal has been made from hay of poorer quality. According to the definitions of the Association of American Feed Control officials, alfalfa meal must not have more than 33 per cent fiber.[10]

It is often impossible to determine without chemical or laboratory analysis whether alfalfa meal has been made from leafy, early-cut hay or from over-ripe, stemmy material. Hence the meal should be purchased on guarantee of composition.

Dehydrated alfalfa meal is usually fully twice as high in carotene as the products made from field-cured hay, and it is also somewhat higher in riboflavin. However, it has practically no vitamin D, while alfalfa meal from field-cured hay has considerable. This lack of vitamin D in the dehydrated product is not of importance in feeding poultry, for the reasons pointed out earlier in this chapter. However, in using the dehydrated products as a vitamin supplement for swine, it must be borne in mind that they do not supply vitamin D, like field-cured hay does.

The carotene content of various lots of alfalfa meal, even dehydrated alfalfa, unfortunately varies widely. Therefore, in the use of these feeds as vitamin A supplements in making formula feeds, the manufacturer should use products of known carotene content. Otherwise, he cannot be sure that his feeds will actually have the desired vitamin A value.

The losses of carotene and vitamin A in feed during storage and methods of greatly reducing the losses have been discussed in Chapter VII. (**195**)

If one has no legume hay available for feeding to his stock, the purchase of alfalfa meal as a substitute may be warranted, but most farmers can grow good legume hay much more cheaply than they can buy alfalfa meal. It must be borne in mind that fine grinding does not change a roughage into a concentrate, nor does it increase its digestibility for animals with good teeth. Any advantage from grinding or chopping hay probably results from a saving in wastage or in getting animals to eat more than they would otherwise consume. The effect of grinding or chopping hay for the various classes of stock is discussed in Chapter IV.

456. Alfalfa leaf meal.—Alfalfa leaf meal, according to the definition of the Association of American Feed Control Officials, is the ground product consisting chiefly of alfalfa leaves. It must be reasonably free from other crop plants, weeds, and mold, and must have at least 20 per cent protein and not more than 18 per cent fiber.[10]

Some years ago considerable alfalfa leaf meal was produced by screening the coarser stemmy portion from alfalfa meal after it was ground. Now there is but little alfalfa leaf meal on the market, and apparently the name is sometimes used

for the entire ground hay when it is cut so early and is of such high quality that it is low in fiber. However, some of the product sold as alfalfa leaf meal exceeds the limit of 18 per cent fiber, as will be noted in Appendix Table I.

457. Alfalfa stem meal.—Alfalfa stem meal is the product screened from ground alfalfa hay when alfalfa leaf meal is made in this manner. It is much lower in protein and higher in fiber than good alfalfa hay, and has a correspondingly lower feeding value. When very finely ground, it may be difficult to distinguish alfalfa stem meal from alfalfa meal, without laboratory examination.

458. Alfalfa hay for dairy cattle.—Good alfalfa hay is unexcelled as a dry roughage for dairy cattle and may be taken as the standard with which other kinds of hay are compared. If good cows have an abundance of well-cured alfalfa hay as part of a balanced ration, they will produce a high yield of milk and will need less grain and other concentrates than when less palatable and efficient roughage is fed. This results in a considerable saving in the cost of milk production.

Often dairymen who are feeding an abundance of good alfalfa hay to their cows use concentrate or grain mixtures which are much higher in protein than actually needed. If the protein-rich mixture costs more than one lower in protein content, such a practice is decidedly uneconomical. It is shown in Chapter XXV that for cows of any usual productive capacity there is no need to add a protein supplement to a ration consisting of corn or other grain plus an abundance of good alfalfa hay, fed as the only roughage. (**1017**)

It is wise to add a phosphorus supplement to a ration consisting of only grain and alfalfa hay (with or without corn or sorghum silage, but without any protein supplement) unless the roughage has been grown on soil rich in phosphorus. (**1035**)

The great differences in feeding value between good and poor hay and between early-cut and late-cut hay have been emphasized in Chapter XIII and in Chapter XIV. (**358, 391–392**)

In some sections of the West alfalfa hay is so much cheaper than other feeds that dairy cows are fed only alfalfa hay during the winter and sometimes even throughout the year. Such a ration is too bulky and low in digestible nutrients for high production and is also very high in protein. Breeding troubles have been attributed to this ration, but experiments have shown that the excess of alfalfa hay and of protein is not responsible for such troubles. Instead, they are commonly due to brucellosis (Bang's disease).

Whether or not it will be most economical to feed only alfalfa hay to good cows in such districts, will depend on the relative price of alfalfa and other feeds and also on the price of milk. (**1028**) Adding corn or sorghum silage to the ration may sometimes be more profitable than adding grain.

The opinion is sometimes stated that alfalfa hay is too laxative for young calves. However, New York and Wisconsin experiments, as well as the experience on innumerable farms, show that alfalfa hay is very satisfactory for dairy calves, right from the start of hay feeding.[11]

If cows are fed alfalfa hay as the only roughage throughout the entire year, without any pasture or other green feed, they may tire of the alfalfa. They will then produce decidedly better results when fed some other roughage in addition, even grass hay of ordinary quality.

Alfalfa hay should be fed after milking, instead of before milking. This is because the flavor of the milk may be injured if alfalfa hay is fed less than about 4 hours before milking time. When cows are fed nothing but alfalfa hay, the butter may be undesirably hard. This condition can be corrected by adding silage to the ration.

459. Alfalfa meal; alfalfa pellets; chopped alfalfa hay for dairy cows.—Alfalfa hay of good quality is eaten by dairy cows with so little waste that it does not pay to go to additional expense to chop it for them. When field-chopped hay is made, it should be chopped as

long as possible. (407) It is shown in Chapter XXV that finely ground hay or alfalfa pellets as the only or the chief roughage for dairy cows is decidedly undesirable. (1052)

When dairy cows receive a ration that includes plenty of legume hay or even good mixed hay, there is no special advantage in adding alfalfa meal, even dehydrated alfalfa, to the concentrate mixture. Alfalfa meal, or ground alfalfa hay, even when made from hay of first-rate quality, is distinctly a roughage and not a concentrate. Average alfalfa meal contains over twice as much fiber as wheat bran and supplies much less total digestible nutrients. It cannot therefore replace any large part of the concentrates needed for high milk production.

In experiments where alfalfa meal has been compared with bran in good rations, the bran has generally had a decidedly higher value per ton.[12] In Kentucky trials in which alfalfa meal was substituted for 23 to 37 per cent of a usual concentrate mixture, the added alfalfa meal was worth about two-thirds as much per pound as the ordinary concentrate mixture.[13] Similar results were secured in Wyoming experiments in which dehydrated alfalfa pellets or meal replaced 20 per cent of the usual concentrate mixture.[14]

If the total amount of feed eaten by cows is increased by *adding* alfalfa pellets or alfalfa meal to a good ration, the milk production will of course be increased somewhat.[15] At the usual price of alfalfa meal or pellets, it might be appreciably more economical to feed a correspondingly greater amount of the ordinary concentrate mixture.

In 3 Oklahoma experiments with prairie hay as the only roughage, 30 per cent of the usual concentrate mixture was replaced with alfalfa meal made from leafy alfalfa and 10 per cent more of this mixture was fed, because of the lower digestible nutrient content of alfalfa meal.[16] The feeding of the alfalfa meal did not increase milk production, and each 100 lbs. of alfalfa meal was worth about as much as 65 lbs. of concentrates.

460. Alfalfa hay for beef cattle.—Alfalfa hay has no superior for feeding beef cattle. Not only is it an excellent roughage for fattening cattle, but also its value for the breeding herd is perhaps even more outstanding. When any reasonable proportion of the roughage consists of well-cured alfalfa hay, one can be sure that there will be no deficiency in quality of protein or in calcium or vitamins.

It is shown in Chapter XXVIII that if fattening cattle are fed a liberal amount of alfalfa hay as the only roughage with corn or other grain, it generally does not pay to add a protein-rich concentrate, such as cottonseed or linseed meal. However, when the cattle are fed corn or sorghum silage in addition to alfalfa hay, this succulent feed is so palatable that they will not eat enough alfalfa to balance the ration completely. To secure the best results, it is then necessary to add a small amount of a protein supplement.

Alfalfa hay may be used as a protein supplement to low-protein roughage, such as corn or sorghum silage, in wintering young beef cattle or breeding cows. However, it will take about 3 lbs. of alfalfa hay to replace 1 lb. of cottonseed meal or soybean oil meal for this purpose, because of the much lower protein content of the hay. (See Chapter XXIX.)

The chopping or grinding of alfalfa hay for beef cattle and the fattening of cattle on alfalfa hay alone, or on alfalfa hay and other roughage, are discussed in Chapter XXVIII.

461. Alfalfa hay for sheep.—Alfalfa hay is such a good feed for sheep that it may be taken as the standard with which other roughages are compared. For sheep feeding, hay that is leafy and fine stemmed should be used, if possible, as it is of decidedly higher value than coarse, stemmy hay. In New Mexico tests, fine leafy alfalfa was worth 39 per cent more per ton than coarser-stemmed hay for fattening lambs when the hay was fed as the only roughage, and 8 to 27 per cent more when sorghum silage was fed in addition.[17]

Lambs cannot be fattened sufficiently for the large markets on alfalfa hay alone, even of the best quality. If it is desired to fatten lambs for marketing late in the winter or in the spring, it may be desirable to feed them hay alone during the first part of the fattening period and later to add grain to the ration.

There may be a greater tendency for the stiff-lamb disease to occur when ewes are fed alfalfa hay as the only roughage in winter, than when other roughages are also fed.

462. Alfalfa hay for horses and mules.—Experience on thousands of farms in the western part of the United States, where alfalfa hay has been used for many years as the only roughage for horses and mules, shows that it is economical and entirely satisfactory when properly fed.

Alfalfa hay for horses should be free from dust or mold and should not be cut until about full bloom, as hay cut earlier may be too laxative. Alfalfa is very palatable to horses, and therefore the amount must be strictly limited, or they will eat too much. Not over 1.0 to 1.1 lbs. daily per 100 lbs. of live weight should be fed work stock. Although alfalfa hay can be fed with entire success as the only roughage, some prefer to use it for but one-third to one-half the daily allowance of hay, the remainder being hay from the grasses.

Several experiments have shown that alfalfa hay is excellent as the only roughage for horses or mules at hard work.[18] When alfalfa is the roughage, less grain is needed to keep them in condition than with average timothy or other grass hay.

A common ration for idle horses in the West is alfalfa hay fed with no grain, but often with what straw the animals will eat.

463. Alfalfa hay, alfalfa meal for swine.—For swine not on pasture, good-quality alfalfa hay and other legume hay is of especial value as a vitamin supplement. The legume hay not only furnishes vitamin A value and vitamin D in addition (if it is field-cured), but it also supplies other vitamins which may be lacking when swine are confined in dry lot, with no green feed.

Such a ration as yellow corn and soybean oil meal, plus minerals, is unsatisfactory for continuous feeding over a long time to brood sows or young pigs in dry lot, because of deficiencies in vitamins. By including a sufficient amount of good alfalfa hay in the ration, these deficiencies are largely corrected and fairly good results are usually secured.

Even such a ration as corn and tankage is decidedly improved for young pigs not on pasture by the addition of alfalfa hay or other legume hay. In 8 experiments 62-lb. pigs fed yellow corn and tankage in dry lot until they were ready for market gained an average of 1.16 lbs. per head daily.[19] The addition of 4 per cent of alfalfa hay to the ration increased the gain to 1.26 lbs. and also reduced the amount of feed required per 100 lbs. gain. In these experiments each 100 lbs. of alfalfa hay saved 112 lbs. corn plus 31 lbs. tankage, without giving it any credit for the increase in rate of gain. This shows how well it pays to provide legume hay for pigs fed such a ration as corn and tankage in dry lot.

If any other grain than yellow corn had been fed in these experiments, the addition of alfalfa hay would have been even more beneficial, for many of the pigs fed grain and tankage, without alfalfa hay, would have been injured by the deficiency of vitamin A. Also, if the pigs had been started on the trials immediately after weaning, those fed yellow corn and tankage would not have made as creditable gains as were made by these 62-lb. pigs. The younger the pigs are when they are put in dry lot without green feed, the greater will be the advantage in supplying them with good legume hay.

The use of legume hay or alfalfa meal as a vitamin supplement in swine feeding is more fully discussed in Chapter XXXIV. Even such a ration as corn, tankage, and alfalfa hay is not quite ideal for young pigs in dry lot. Still better results will be secured by using one of the supplemental mixtures there recommended.

Alfalfa stem meal or poor quality alfalfa meal should not be used to protect swine in dry lot against vitamin deficiencies, because of the low vitamin content.

464. Alfalfa hay as the only supplement to grain for swine.—Alfalfa hay is fairly rich in protein, and the protein is also of such quality that it helps to correct the deficiencies in the proteins of the grains. The question therefore arises as to whether alfalfa hay is satisfactory when used as the only protein supplement to the grains in swine feeding. A ration consisting only of legume hay and grain is satisfactory for wintering pregnant sows a year of age or more, if the hay is of excellent quality. For younger sows during pregnancy and also for all sows when they are suckling their pigs, a small amount of a more concentrated protein supplement should be added to the ration.

Growing and fattening pigs have less capacity to consume hay than have older swine. Also, their needs for protein are relatively large. While the addition of alfalfa hay to a full feed of corn for pigs will produce decidedly better results than corn alone, the gains are much less rapid and also less economical than when a more concentrated and more efficient protein supplement is fed in addition.

For example, in 14 experiments well-grown pigs, averaging 102 lbs. in weight at the start, gained but 1.08 lbs. per head daily on a full feed of corn supplemented by only alfalfa hay.[20] Others fed corn and tankage, with no alfalfa hay, gained 1.51 lbs. a day and required considerably less feed per 100 lbs. gain. In these trials each 100 lbs. of tankage replaced 194 lbs. corn plus 174 lbs. of hay, without considering the large increase in rate of gain.

Still better results would have been secured with these pigs, fed in dry lot, if alfalfa hay had been added to the ration of corn and tankage. Also, if the pigs fed only corn and alfalfa hay had not been well-grown when placed on this ration the results would not have been nearly so good as were secured in these tests.[21] Young pigs need very much more protein than is provided by a ration consisting only of corn and excellent alfalfa hay.

Alfalfa hay produces somewhat better results when fed as the only protein supplement to other grains that are higher than corn in protein. However, unless efficient protein supplements are unusually high in price, it is usually economical to add such a supplement to a ration of alfalfa hay and a full feed of barley, wheat, oats, kafir, or rye, especially for pigs under 100 to 125 lbs. in weight.[22]

465. Alfalfa meal, alfalfa hay for poultry.—Alfalfa meal is used extensively as a vitamin supplement in poultry rations. Not only does alfalfa meal supply carotene, which furnishes vitamin A, but it also helps provide riboflavin and other B-complex vitamins, including one of the unidentified vitamins. (222) In addition, alfalfa supplies vitamin K, which in poultry is necessary to prevent hemorrhagic trouble. (225) Only 1 to 2 per cent of good-quality alfalfa meal in the ration furnishes sufficient of this vitamin.

Alfalfa meal also supplies xanthophylls, yellow-colored compounds that give the yellow color, desired on meat markets, to the skin and shanks of poultry. (14)

Commonly, only 2 to 5 per cent of alfalfa is included in formula mashes for chicks and hens, as this proportion of high-quality alfalfa meal is ample. Recent investigations have shown that sometimes both dehydrated alfalfa and sun-cured alfalfa contain a substance which depresses the growth of chicks.[23] However, this depression does not occur unless the percentage of alfalfa meal in the ration is more than 5 per cent.

Even if the alfalfa meal does not contain this growth-depressing factor, the net-energy value of a ration for chickens is decreased when alfalfa meal forms more than about 5 per cent of the entire ration. Turkeys can utilize a larger proportion of alfalfa meal efficiently, good results being obtained with as much as 18 per cent in rations for poults up to

8 weeks of age, and even more for older birds.[24]

Generally, dehydrated alfalfa meal is preferable to sun-dried alfalfa meal for poultry, because it is usually much higher in carotene and other vitamins. However, when poultry rations are mixed on the farm and high-quality alfalfa hay is available, the vitamin A needs of chickens can ordinarily be met by including 5 to 10 per cent of the ground hay in the ration.

ALFALFA IS UNEXCELLED FOR SWINE PASTURE

Alfalfa furnishes pasture over a longer season than most other forages, and it is rich in protein, vitamins, and calcium.

When alfalfa hay of excellent quality is available on the farm, it may be fed to hens in racks, instead of mixing ground hay or alfalfa meal in the mash. There is, however, danger that they will not eat enough of the hay to meet their need for vitamin A.

466. Alfalfa for pasture.—Alfalfa is one of the best pasture crops for swine, horses, and poultry. Cattle and sheep are also often pastured on alfalfa, but it may cause serious trouble from bloat. For pasturing cattle or sheep, it is much safer to use a mixture of alfalfa with a considerable proportion of such grasses as bromegrass, timothy, or orchard grass. Also, trouble from bloat can generally be avoided or reduced by following the practices mentioned previously. (**49**)

Heavy continuous grazing of alfalfa is very apt to injure the stand, and therefore rotation grazing is decidedly preferable. Except possibly where alfalfa thrives best, it is wise to provide a sufficient area of pasture so that considerable alfalfa will grow up to be cut for hay once or twice during the season. A still better plan is to pasture a given field during only part of the season, making one or more cuttings of hay at the usual stage of maturity. Fields should never be pastured until the stand has become well established, and animals should be kept off when the ground is soft, muddy, or frozen. To lessen winter injury in the North, alfalfa should not be grazed closely in the fall. Grazing frosted or frozen alfalfa is believed to cause digestive trouble, which is sometimes serious.

Alfalfa is excelled only by Ladino clover as a pasture crop for swine. Alfalfa furnishes pasture over a longer sea-

son than most other forages, starting early in the spring and remaining green and succulent in midsummer when bluegrass has dried up and even red clover has become hard and woody. The number of pigs should be restricted so as to avoid too close grazing and consequently injury to the stand of alfalfa. Ordinarily, an acre of good alfalfa should carry 8 to 10 pigs weighing 100 lbs. each, with little danger to the stand. Under very favorable conditions, even heavier grazing may be practiced.

The value of alfalfa pasture for pigs is shown by the results of 14 experiments in which alfalfa has been compared with rape pasture, which is the best single temporary pasture crop for swine where it thrives.[25] Spring pigs full-fed corn and a good supplement on the alfalfa pasture gained a trifle more rapidly than others on rape pasture. Also, 10 lbs. less feed was required per 100 lbs. gain on the alfalfa pasture. In addition, over a ton of hay per acre was cut from the alfalfa lots. A further advantage of alfalfa over rape is that rape is not a legume, and therefore does not add nitrogen to the soil. Rape is an annual, and the cost of growing it is therefore somewhat higher than the cost of alfalfa pasture in sections where a seeding of alfalfa will last for 3 years or more.

467. Alfalfa for silage.—Alfalfa and mixtures of alfalfa and grass are used more frequently in this country than any other hay crops for making hay-crop silage, or so-called "grass silage." Even a pure stand of alfalfa generally makes very satisfactory silage when one of the special methods is used which have been described in Chapter XV. It is there pointed out that except in very favorable hay-making weather, making alfalfa into silage conserves the nutritive value of the crop better than in making it into hay by ordinary methods. Making part of the alfalfa crop into silage is of advantage where the weather at haying time is apt to be so rainy that it is difficult to cure hay satisfactorily. Also, if one wishes to produce market milk with the maximum yellow color and vitamin A value in winter, alfalfa silage or other "grass silage" is desirable as part of the roughage, because it is higher than alfalfa hay or corn silage in carotene.

The relative values of alfalfa and other hay-crop silages in comparison with corn silage have been discussed previously. (**436–441**)

468. Alfalfa as a soiling crop.—Alfalfa is one of the best soiling crops, owing to the large yields and to the fact that under proper management it will furnish good feed throughout the entire summer. Much more forage, even twice as much in some cases, is secured from a given acreage as a soiling crop, than when pastured. The use of soiling crops instead of pasture has been discussed in Chapter XIII. (386–387)

469. Alfalfa-grass mixtures.—Except in regions especially well adapted to alfalfa, it is generally best to seed alfalfa in combination with a grass, unless there is a need or demand for pure alfalfa hay. Alfalfa will last longer in such a combination than in a pure stand, because the grass helps prevent winter injury to the alfalfa through heaving. The combination therefore usually yields more forage per acre than alfalfa alone. In addition, an alfalfa-grass mixture resists erosion and the invasion of weeds better than alfalfa alone. Also, such a combination is much safer than alfalfa for pasturing cattle or sheep. There is usually little danger from bloat in pasturing a mixture of alfalfa and grass, if at least one-third to one-half the forage is grass.

Early-cut mixed alfalfa-and-grass hay containing at least one-half alfalfa is fully as palatable to cattle as pure alfalfa. Also, the feeding value is as high for the mixed hay, except that it is, of course, lower in protein than pure alfalfa. Hence, a somewhat greater amount of protein supplement may be needed to balance the ration when such mixed hay is fed.

Of course, first-rate alfalfa hay is much superior to lower grade alfalfa-grass hay. For example, in a recent trial by the United States Department of Agriculture dairy heifers fed U.S. No. 1 alfalfa hay as the only feed gained 90 per cent more than others fed U.S. No.

2 alfalfa-timothy hay that had 34 to 37 per cent fiber.[26]

For swine and poultry, pure alfalfa hay is to be preferred, as it is higher in vitamin content and alfalfa has its greatest value in swine and poultry rations as a source of vitamins. Also, for sheep mixed hay consisting chiefly of alfalfa is better than that made up mostly of grass. For horses and mules, the opposite is true; a mixture high in grass is rated above one high in alfalfa.

Where a field is to be in hay or pasture for 3 years or more, the combination of alfalfa and bromegrass has generally proven superior to alfalfa and timothy or alfalfa and orchard grass in the north central and northeastern states. In a short rotation, timothy is better than bromegrass with alfalfa, because brome is established more slowly. Farther south, alfalfa and orchard grass make an excellent mixture. In the Northwest, alfalfa and crested wheatgrass may be equal or superior to alfalfa and bromegrass.

Bromegrass is so palatable to stock that they are less apt to kill the alfalfa in an alfalfa-brome mixture, than when grazing a pure stand of alfalfa. Another advantage of this mixture is that when some of the alfalfa plants die out, the bromegrass fills in the vacant spaces.

Such a pasture combination as alfalfa-brome is of especial value for dairy cows, since it provides an abundance of highly-palatable and nutritious feed in midsummer when permanent bluegrass pasture is often dried up. In Indiana trials, for example, twice as large an area of bluegrass pasture was needed to provide feed for a given number of cows, as was required of alfalfa-brome pasture.[27] Although 0.3 lb. more concentrates were fed per head daily to the cows on bluegrass pasture, they produced 10 per cent less milk and also did not maintain their weights so well.

III. The Clovers

470. Medium red clover.—Medium red clover (*Trifolium pratense*), commonly called merely red clover, is generally grown in combination with timothy in the United States. For this reason the two are combined in the official crop reports. Clover and timothy is still the most important hay crop in all but a few of the northern states from Iowa eastward. For the entire country the acreage of clover and timothy nearly equals that of alfalfa, but the yield of alfalfa per acre is so much higher that a much greater tonnage of alfalfa hay is produced.

Red clover and timothy are commonly seeded in small grain. The first cutting of hay the year following seeding will have a large proportion of clover, if conditions are favorable, and the second cutting will be mostly clover. The proportion of clover will be much less the next year, except where clover thrives unusually well, and the following year the crop will be nearly all timothy. When grown alone, red clover is usually treated as a biennial.

The value of clover and other legumes in increasing the yields of other crops through the nitrogen they add to the soil is shown in a striking manner by extensive experiments at the Ohio, Pennsylvania, and Missouri Stations.[28] In these studies short-time rotations which included clover have been compared with continuous cropping to corn, oats, wheat, etc. The increases in the value of the grain crops due to the growing of clover were worth even more than the actual value of the clover harvested. Thus, the hay value of the clover crop was less than half its total value.

Red clover does best on well-drained soils rich in lime, but it grows satisfactorily on fields which are a little too acid or not quite well enough drained for alfalfa. It stands severe winters better than alfalfa but does not endure drouth so well, as the roots do not go so deep. On fields that are not uniformly well drained, alsike clover is commonly seeded with red clover and timothy, for alsike will do better on the poorly-drained spots.

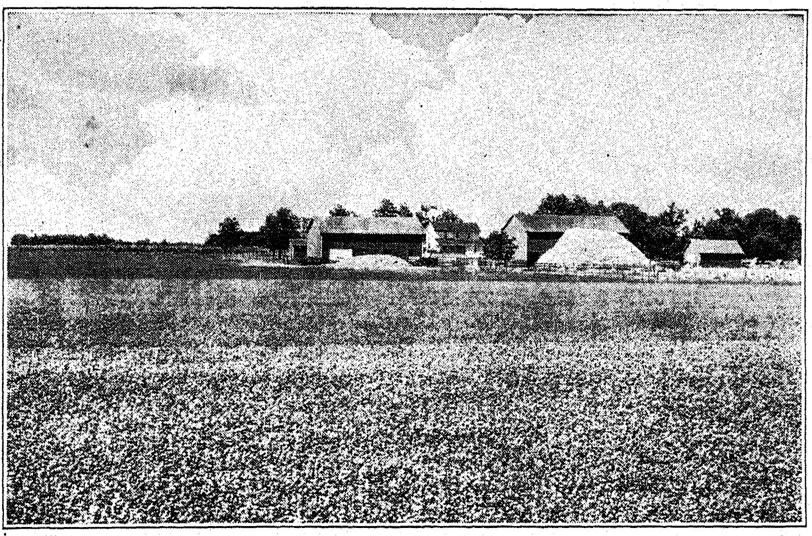
Red clover generally yields a heavy first crop of hay and a much lighter second crop, which is often allowed to mature for seed. When seeded in the spring with a small grain crop, as is the common

practice, clover and timothy will furnish some pasturage the same fall, or even a hay crop if the season is especially favorable. In the southern states, where red clover does not thrive during the heat of summer, it is sometimes grown as a winter annual, the first crop being cut in the spring and the second in early summer.

In seeding red clover, one should be sure to use a strain that is well adapted to the particular locality. Where injury from anthracnose is serious, a resistant variety should be chosen. Red clover from central and southern Europe has been found unsuitable for most clover-growing sections of the United States. Sometimes farmers abandon the growing of red clover because of failure to secure good stands. In most cases such trouble is caused by a lack of lime, phosphate, and possibly potash, or by the use of seed that is not adapted to the locality.

Occasionally, clover is covered with a powdery mildew, and farmers wonder whether there will be any danger in using it for hay or pasture. Apparently, this will not injure stock at all.

471. Red clover hay; mixed clover and timothy hay.—Red clover hay and mixed hay containing a large proportion of clover is second only to alfalfa hay in value for livestock. When cut at the usual stage of maturity, pure red clover hay supplies only about two-thirds as much digestible protein as alfalfa hay. Therefore, in feeding dairy cows and other classes of stock, a somewhat larger amount of protein supplements is often needed with red clover hay than with alfalfa.



A Fine Field of Red Clover for Hay

Red clover, generally grown in combination with timothy, is a very important legume for hay in most of the northcentral and northeastern states.

The difference in protein content and a slightly greater palatability are the chief reasons why alfalfa hay usually sells at a higher price than clover hay of equal quality. Clover hay supplies a trifle more total digestible nutrients than alfalfa and slightly surpasses it in net energy.

Considering both the yield and the quality of the hay, red clover should be cut for hay not later than full bloom.[29] A good plan is to start cutting when about half the plants are in bloom and finish by the full-bloom stage. Such hay will be richer in protein and total digestible nutrients and also more palatable than if cut later. Also, if the first crop is

cut at this stage, the yield of hay or seed in the second crop will be much larger.

The value of mixed clover-and-timothy hay will depend on the proportion of clover present and on the stage of maturity at which it is cut. The more clover there is in the hay, the greater will be its value for all classes of stock except horses. Late-cut mixed hay is a poor roughage for dairy cows or sheep.

Red clover hay, alsike clover hay, or mixed hay consisting chiefly of these legumes is excellent for dairy cattle,[30] beef cattle,[31] and sheep.[32] Except for the fact that a slightly larger amount of protein supplement may be needed to balance the ration when clover hay is fed, it has proven equal or nearly equal to alfalfa hay in feeding experiments with these classes of stock. If the rest of the ration lacks protein, then clover hay will be definitely inferior to alfalfa, which supplies more protein.

Clover hay which is well cured and free from dust or mold is satisfactory for horses and mules, while that of poor quality is not suitable for them.[33] Second-crop clover hay may cause slobbering, for some unknown reason.

Red or alsike clover hay of good quality is a satisfactory substitute for alfalfa hay for pigs or for breeding swine. In Wisconsin and Ohio experiments chopped red clover hay equalled alfalfa hay when used as a vitamin supplement for growing and fattening pigs.[34] If used as the only supplement to grain for swine, clover hay is less efficient than alfalfa hay, for it is less palatable, as well as being lower in protein and calcium.

Clover hay is used for poultry much less commonly than alfalfa, because it usually has less carotene. However, early-cut, well-cured clover hay may be substituted for alfalfa and used in the same manner.

472. Clover for pasture.—Red clover is one of the best pasture crops to be grown in rotations, but it does not usually persist in permanent pastures. For pasturing cattle and sheep, red clover is safer than alfalfa, because there is less danger from bloat. However, with a pure stand of clover, the precautions stated in Chapter II should be taken to avoid this trouble. With mixed clover-and-timothy pasture, which is used for such stock much oftener than pure clover, there is little danger from bloat.

In the northern and central states, red clover is one of the best pasture crops for swine, being excelled only by alfalfa and Ladino clover. In several experiments pigs gained as rapidly on red clover pasture as on alfalfa and required only a trifle more feed per 100 lbs. gain, and in other experiments red clover pasture was slightly superior to rape for swine pasture.[35] There is somewhat more advantage in feeding pigs on clover pasture a protein supplement, in addition to corn or other grain, than there is in the case of alfalfa pasture, for clover is not so rich as alfalfa in protein.

Red clover should not be grazed too closely, or the plants may be killed. Clipping the pasture at the usual time for the first cutting of hay will stimulate new growth.

Red clover or alsike clover is very satisfactory for poultry pasture, being excelled only by alfalfa or by Ladino clover.

473. Clover for silage; as a soiling crop.—Clover or mixed clover and timothy is often used for hay-crop silage and makes good silage when one of the special methods is used which have been described in the previous chapter. The value of such silage in comparison with corn silage for the various classes of stock has been discussed there.

These crops are sometimes used as soiling crops, being cut and fed green to stock. (386) When red clover is cut early, it may furnish 3 or 4 cuttings of green feed a year.

474. Mammoth clover.—This clover (*Trifolium pratense perenne*) is similar to red clover, except that is grows ranker, has coarser stems, and blooms 1 to 2 weeks later. It usually lives 3 years or more and does better than red clover on poor or sandy soil. As it is coarser, the hay is not quite equal to red clover. Since mammoth clover yields only one cutting a season, it is frequently pastured

for several weeks in early spring and then allowed to grow up for hay.

475. Alsike clover.—Alsike clover (*Trifolium hybridum*) flourishes on land too wet or too acid for red clover or alfalfa, if the summers are not too hot. It is somewhat longer lived than red clover, and in an open sward may tend to reseed itself to some extent. Since alsike clover yields but one cutting of hay with some fall pasturage, it is excelled by red clover where the latter thrives. It should be seeded with timothy or other grasses to support the weak stems. Many farmers include some alsike in their seedings of red clover and timothy, especially on the wetter fields. Alsike clover hay is fine-stemmed and fully equal to red clover in value. This clover was once supposed to be a hybrid between red clover and white clover.

476. White clover.—The common types of white clover (*Trifolium repens*) are primarily pasture plants, as they are too low growing to yield hay. White clover thrives best on the heavier soils and where the supply of moisture is ample. It is a moderately short-lived perennial which spreads by means of runners and also reseeds itself under favorable conditions, even when closely grazed. In the North white clover is often important in mixed pastures, forming a dense mat and furnishing feed throughout the growing season. In the South it nearly disappears in summer but reappears in the fall, furnishing winter pasturage and thus combining well with Bermuda grass. When one wishes to maintain white clover in a pasture, it is essential that the pasture be closely grazed. Otherwise, the tall-growing grasses will kill out the low-growing clover.

In the southern states Louisiana white clover and other strains which are taller than ordinary white clover are widely used in permanent pasture mixtures.[36] They generally behave as winter annuals, usually reseeding themselves.

The white clover which often appears spontaneously in many pastures under favorable conditions is usually a wild type with smaller leaves than the common variety (known as "white Dutch clover"). Such wild white clover is longer-lived and apparently better adapted for seeding in permanent pasture mixtures.

477. Ladino clover.—During recent years, Ladino clover, a large-growing variety of white clover introduced from Italy, has become a very important legume in pasture, hay, and silage mixtures in this country.

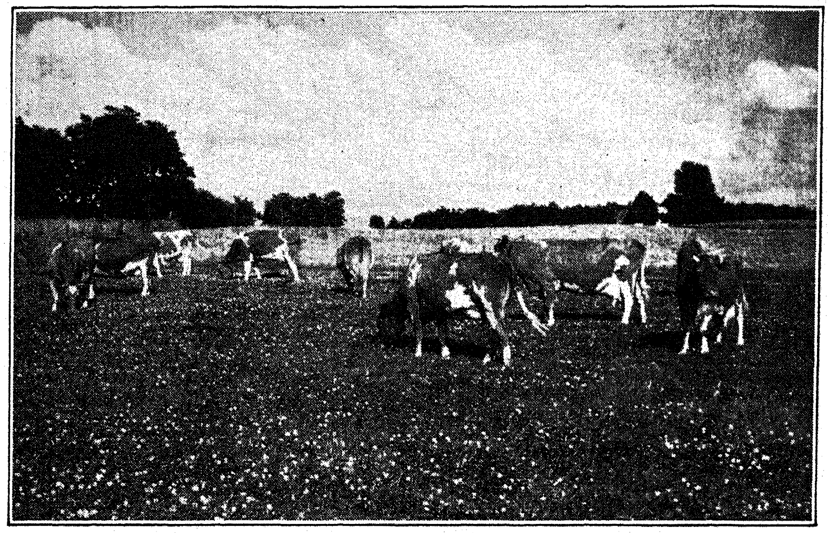
Ladino clover does best on soils well supplied with moisture. Like alsike clover, it will grow on land too wet or somewhat too acid for alfalfa or red clover, but it thrives better when soil acidity is corrected by liming. As it is rather shallow rooted, Ladino clover does not stand drouth so well as does alfalfa. It thrives especially well in the northern states, but is also grown in other sections, including some of the western irrigated districts.

Ladino clover is easily established by seeding in small grain, and the plants spread by means of creeping fleshy stems which root at the joints. It has no upright stalks, as do the other hay-crop clovers or alfalfa. The leaf stems grow up to a height of 10 to 14 inches or even more under favorable conditions. Under proper management Ladino clover will sometimes last several years in a pasture combination, except in some of the extreme northern areas of the United States and in the southernmost states. When the plants die out, Ladino frequently reseeds itself, as some seed is generally produced in a pasture. In the South, Ladino behaves as a winter annual.

Except for poultry pasture and perhaps for swine pasture, it should be seeded with a grass, usually bromegrass, orchard grass, or timothy in the North, and Dallis grass, Bermuda grass, or tall fescue in the South. The clover endures better in a mixture with grass than when seeded alone, as it is less subject to winter injury. Also, a Ladino-grass pasture mixture that has at least about 40 per cent of grass is much less apt to cause bloat in cattle or sheep than pure Ladino pasture. Where alfalfa thrives, it is a good plan to include a little alfalfa in Ladino-grass mixtures.

Ladino pasture is very palatable, and it is unusually rich in protein, low in fiber, and high in total digestible nutrients. On the dry matter basis, Ladino pasture has about 24 per cent protein and only 15 per cent fiber. An especial advantage of Ladino clover for pasture is that it makes more of its growth in summer, and especially in midsummer, than any other perennial grass or legume, except alfalfa.

Unlike ordinary white clover, Ladino pasture ranks ahead of all other pasture crops, because of its great palatability to poultry and its high yield.[37] For swine, Ladino pasture is equal or superior to alfalfa.[38] Ladino clover forage is higher in water than most other legume forage. Perhaps for this reason, dairy cows on Ladino pasture relish some dry hay in addition. Early in the season, Ladino pasture is apt to be very laxative, unless cattle are accustomed to it gradually, or fed hay in addition.



LADINO CLOVER AND GRASS PASTURE

Ladino clover in combination with timothy, orchard grass, or other grasses, provides excellent long-season grazing. (From New York State College of Agriculture, Cornell University.)

dino is killed by continuous close grazing. It should therefore be grazed in rotation, with a rest period of 2 to 3 weeks for new growth between each grazing, or else it should not be grazed too heavily. Ladino should not be grazed more closely than 2 to 3 inches, and in the fall some growth should be left in cold climates for winter protection. If Ladino clover is pastured when the plants and ground are frozen, the stock are apt to injure the fleshy creeping stems severely, through trampling.

Ladino-grass pasture is excellent for all classes of stock and provides forage over a long season. For poultry, pure La-

For hay or silage it is important to cut a Ladino-grass mixture when the Ladino is in early bloom. Otherwise, the grass, which grows much taller when it heads out, is apt to choke out the Ladino. It is difficult to mow a pure stand of Ladino clover unless the mower is in excellent condition, because of the dense growth and the softness of the leaf stems. Also, pure Ladino clover is hard to cure, because the leaves mat together. These difficulties are largely avoided by growing it in combination with grass.

Ladino or Ladino-grass hay is excellent for dairy cows, beef cattle, or sheep. In a New York experiment pure

Ladino hay tended to increase the tendency for oxidized flavor to develop in pasteurized milk on storage, perhaps due to a lower content of vitamin E in the fat.[39] Ladino pasture did not injure the flavor of milk in a Georgia trial.[40]

Early-cut Ladino or Ladino-grass hay or dehydrated meal can be used as a vitamin supplement for poultry or swine in the same manner as alfalfa.[41]

478. Sweet clover.—Sweet clover is an important crop, especially for soil improvement and for pasture, in extensive areas of the United States. It is grown chiefly in the eastern part of the Great Plains, in the corn belt, and in certain districts of the South. The kinds mostly grown are biennial white-flowered sweet clover (*Melilotus alba*) and the biennial yellow-flowered varieties (*Melilotus officinalis*). These varieties are usually seeded in spring grain, and reach maturity and die in August of the following year.

Annual varieties, especially Hubam, are grown in certain areas, mostly for soil improvement. For pasture or hay they yield much less than biennial sweet clover.

Sweet clover stands drouth nearly as well as does alfalfa and will grow on soil too poorly drained or too low in fertility for alfalfa or red clover. However, it requires an ample supply of lime and proper inoculation. In the West it is a good crop for alkali or hard adobe soils. In the North sweet clover is subject to injury from heaving during the winter, the same as alfalfa.

Yellow sweet clover stands drouth and other adverse conditions somewhat better than biennial white sweet clover, and has increased in the Great Plains for this reason. It is finer stemmed, blooms about two weeks earlier, and does not furnish pasture so long the second year.

479. Sweet clover for pasture.—Sweet clover is used chiefly for pasture, especially as a supplement to permanent pasture. Certain later-maturing varieties of biennial white sweet clover are superior to the common kind for pasture, as they provide pasture over a longer period the second year.

At first stock usually dislike sweet clover, on account of the bitter taste, because of the coumarin it contains, but generally they soon become accustomed to it, especially if started on it in the spring, when it is less bitter. Often they will industriously search out every spot of grass and even weeds in the pasture, grazing them to the ground before hunger forces them to the sweet clover. In spite of this lack of palatability, stock usually do well on sweet clover. Sweet clover is less apt than alfalfa to cause bloat in cattle or sheep, but the danger should be guarded against by taking the precautions discussed previously. (49)

The first season's growth of sweet clover may be pastured after it is 8 to 10 inches high and until frost, but close grazing will reduce the yield the following year. The second season the crop will furnish grazing from early spring until the plants die in August, or until they become too woody. By seeding sweet clover in the spring grain each year, it is often possible, if the growth of the first-year crop is good, to pasture the stock on it by the time the second-year crop is exhausted. It will sometimes be necessary to furnish other feed for a brief period. In the southern states second-year and first-year sweet clover, in combination with annual lespedeza, will furnish pasture throughout the entire season.[42]

Some farmers seed sweet clover in the spring without a nurse crop, as a hay or pasture crop for the first season. When thus seeded alone, yields of 1 to 3 tons of hay per acre are secured under good conditions.

In the spring of the second year, grazing should start when the plants are 6 to 8 inches tall, and enough stock should be kept on the field to keep the crop grazed down. If necessary, it should be clipped high, to keep it from blossoming. If it grows up and begins to blossom, it becomes woody and unpalatable and will also set seed and die. As the early growth of sweet clover is very laxative, it is a good plan to supply

stock on such pasture with hay in addition, to prevent scouring.

Sweet clover pasture is particularly useful for dairy cows in July and August when bluegrass pasture is apt to be parched. To furnish pasture at this season, a second-year crop must be closely grazed in the period of rapid growth in the spring. There has been but little trouble from sweet clover producing a noticeable flavor in milk, though sometimes there is a slight change on sweet clover pasture. In South Dakota trials sweet clover pasture was slightly superior to alfalfa and decidedly better than Sudan grass for dairy cows.[43] However, in Wisconsin tests yearling heifers did poorly on sweet clover pasture, apparently because they would not eat enough of it.[44]

Sweet clover pasture has given good results with beef cattle, sheep, and swine. In tests in eastern Washington mixed sweet clover and grass pasture was equal to alfalfa-grass pasture for beef production.[45] Swine take to sweet clover a little less readily than do cattle, but usually become accustomed to it after a time. Experiments show, however, that alfalfa, Ladino clover, red clover, or rape is superior to sweet clover for swine pasture, where these crops thrive.[46]

480. Sweet clover hay; sweet-clover disease.—As a hay crop, sweet clover is inferior to alfalfa or red clover, without considering the danger from sweet-clover poisoning mentioned later.[47] Where sweet clover seeded in spring grain makes sufficient growth after the grain is harvested, it may be cut for hay the same fall, though this will often reduce the yield next year. This crop cures much more readily than the rank growth of the second season and may make hay nearly equal to alfalfa, except for the grain stubble present.

The growth of sweet clover is so rank the second year that it is often difficult to make it into good hay, especially in the humid regions. The fine leaves tend to dry out and shatter before the juicy stems cure sufficiently. In the semi-arid districts the crop is finer stemmed, and the weather is usually better for hay making. Even if the sweet

DAIRY COWS ON SWEET CLOVER PASTURE

If closely grazed during the period of rapid growth in the spring, second-year sweet clover will furnish good pasture in midsummer, as it stands hot weather and drouth well.

clover is cut early and with the mower set to leave a very high stubble, so as to save the buds on the lower parts of the stems, a worth-while second crop is not generally obtained.

Well-cured first-year sweet clover hay usually is about equal to alfalfa hay for dairy cattle, beef cattle, and sheep. It can also be used like alfalfa as a vitamin supplement for swine and poultry. Second-year hay is generally of much lower value. There is apt to be more waste, because of its steminess, and also there is much more danger of it causing sweet-clover disease.

Sweet clover hay and also sweet clover silage which have undergone spoilage may cause *sweet-clover disease.* In this disease the blood loses its power to clot, and the animals may die from internal hemorrhages or may bleed to death from minor wounds. The disease occurs most frequently in young cattle, and rarely affects horses and sheep. The disease is caused by a poisonous compound, dicoumerol, formed when sweet clover spoils, from the coumarin in the plants.[48]

The disease is apparently produced only by moldy or spoiled sweet clover hay or silage, although the spoilage is not always visible. The trouble may be prevented or lessened by feeding sweet clover hay with at least twice as much other roughage, or by alternating it with other roughage in periods of 10 days or 2 weeks, the sweet clover being fed continuously for only this length of time.[49]

481. Sweet clover as a soiling crop or for silage.—Sweet clover is sometimes used as a soiling crop, especially for dairy cows, to supplement short pasture. Sweet clover may be made into silage by using one of the special methods for making hay-crop silage. However, the sweet-clover disease may be caused not only by spoiled sweet clover hay, but also by spoiled silage.

482. Crimson clover.—This annual clover (*Trifolium incarnatum*) is the most important winter annual legume in the southern states. It is grown chiefly in the southeastern states, along the Atlantic seaboard as far north as New Jersey, and in the Pacific Coast region. Crimson clover is widely used in these regions as a winter green manuring and cover crop. It is also important for pasture and hay, and is sometimes used for silage or as a soiling crop. In the extreme North, where the summers are cool and moist, it can be seeded in the spring.

Crimson clover thrives both on sandy soil and also on clay land, if well drained. When it is grown as a winter annual, the crop can be harvested or plowed under as manure early enough so that other crops may be raised the same year.

For temporary winter pasture in the South, crimson clover is commonly seeded with winter grain or with rye grass. If sufficient fall growth is made, the crop will furnish late fall pasture and some winter feed, and then provide excellent spring pasture. Crimson clover is often seeded between the rows of cotton, corn, or sorghum at the last cultivation, as a winter cover crop or for pasture.

Though crimson clover produces plenty of seed in a permanent pasture, the stand of ordinary crimson clover cannot be maintained without reseeding. This is because the seeds germinate readily after the first rain, and the seedlings are usually killed by a dry spell that follows.

To avoid this, reseeding varieties, especially Dixie, have been developed, which have a considerable proportion of hard seeds. For this reason, the seeds germinate over a long period in the fall, and such crimson clover will reseed itself in a permanent pasture, when grown with such grasses as Dallis grass, Bermuda grass, or tall fescue.

For hay, crimson clover should be cut by the time the flowers at the base of the most advanced heads have faded. Cut at this stage, crimson clover hay is about equal to red clover hay. Late-cut hay may injure horses and mules if fed as the chief roughage, for the minute barbed hairs on the blossom heads and stems are then hard and wiry. These hairs may mat together in the digestive

tract, plugging the intestine. To avoid such trouble with late-cut hay, it should be fed with other roughage, or else should be wet thoroughly some hours before feeding it.

Crimson clover silage, made with molasses or phosphoric acid as a preservative, was very satisfactory for dairy or beef cattle in Tennessee tests.[50]

483. Other clovers.—*Alyce clover* (*Alsicarpus vaginalis*) is an annual legume which is used for hay or late summer and fall pasture in some sections of the South. It requires a well-drained, fertile soil. Alyce clover hay equalled annual lespedeza hay in Louisiana trials with dairy cows and in a Mississippi test with beef cattle.[51] In a Florida trial with beef steers it was superior to prairie hay but not so good as alfalfa.[52]

In Florida experiments Alyce clover furnished good pasturage for cows, but for only a short time.[53] Pearl millet was more productive.

Berseem, or Egyptian clover (*Trifolium alexandrinum*), is an annual clover which is adapted to hot climates, growing during the winter season when alfalfa is dormant. It is of much importance in Egypt as a hay crop, as a green soiling crop, and for green manure. Berseem is adapted to such sections of the United States as the Imperial Valley in California. It may be cut several times a season and produces heavy yields under favorable conditions.

The *bur clovers* are low-growing winter annuals that furnish good pasturage in mild regions. They combine well with Bermuda grass, furnishing feed when that grass is dormant in winter, and reseeding unless grazed too closely. In the southern Coastal Plain bur clover offers no advantage for pasture over Dixie crimson clover.[54] Even on land where summer-cultivated crops are grown, bur clover often volunteers in the fall, if once sown. To be sure of its reseeding, alternate strips of the field may be left unplowed to ripen seed.

Two varieties of bur clover are chiefly grown, southern or spotted bur clover (*Medicago arabica*) and California or toothed bur clover (*M. hispida*). Both are more closely related to alfalfa than to the true clovers.

Button clover (*Medicago orbicularis*), is closely related to bur clover. In Tennessee tests it has given promising results as a reseeding winter annual in permanent pastures.[55]

The *hop clovers* (*Trifolium procumbens* and *dubium*) are annual, low-growing clovers that grow wild in various sections and are of importance in permanent pastures in some areas of the South and on the northern Pacific slope.[56] They furnish good early grazing, but disappear in summer.

Persian clover (*Trifolium resupinatum*), a winter annual clover, is a valuable pasture and hay plant of Persia and Egypt and has been found useful in our southern states.[57] Once established with grasses and properly fertilized, it reseeds. It is best adapted to low-lying, heavy, moist soils. It furnishes grazing earlier in the spring than white clover but does not last so long.

Rose clover (*Trifolium hirtum*), an annual clover, which is shorter than crimson clover, reseeds itself and has given good results for reseeding range land in California.[58]

Strawberry clover (*Trifolium fragiferum*) resembles white clover, but has pink flowers. It thrives on soil too alkaline or wet for other legumes and is important in certain western irrigated districts for pasture. In Colorado strawberry clover on a wet seepage field provided excellent pasture for dairy cattle.[59]

Subterranean clover (*Trifolium subterraneum*) is a winter annual which somewhat resembles bur clover. It is an important pasture crop in certain districts of Australia and is adapted to some areas in the southern states and to the coast region of Oregon and Washington. In Australia breeding troubles have been caused in sheep grazing subterranean clover with little grass in the mixture, due to estrogenic hormone in the clover.

IV. Soybeans for Forage

484. Importance of soybeans.—Soybeans (*Glycine max*) have become one of our very important crops, especially in the heart of the corn belt. In recent years 16,000,000 acres or more have been grown annually for all purposes in the United States. This is far greater than the acreage of any of our other annual legume crops. In the leading soybean-growing states—Illinois, Indiana, Minnesota, and Missouri—soybeans are raised on 10 to 21 per cent of the entire crop acreage.

Over 88 per cent of the entire acreage of soybeans is raised for seed, chiefly for the production of soybean oil and soybean oil meal. About 6 per cent of the acreage is grown for hay, and 6

per cent for grazing or as a green manure crop to be plowed under. The uses and value of soybean seed and soybean oil meal for stock feeding are discussed in Chapter XXII.

Soybeans thrive in practically all districts where corn can be grown. They are drouth resistant, are adapted to a wide range of soils, and will do well on soil too sour for alfalfa. Soybeans stand considerable frost, and early varieties can be grown in the northern part of the corn belt. In the southern states on very poor land or on very heavy clays, they are excelled by cowpeas.

485. Soybeans for hay.—Soybeans are often used for hay in the corn belt and other soybean-growing districts. Somewhat over a million acres a year are grown for hay in the United States, with an annual yield of 1.0 to 1.2 tons per acre. Under favorable conditions, soybeans yield up to 2 tons or more per acre of palatable hay which is as rich as alfalfa in protein and is an excellent substitute for alfalfa or clover.

Some farmers include soybeans for hay in their regular crop rotations. Others grow soybeans for hay as a substitute for alfalfa or clover when these crops winterkill. It is generally the best crop for this purpose in sections where soybeans thrive and where the fall weather is suitable for haymaking.

The portion of well-cured soybean hay that is eaten by stock is about equal to alfalfa or clover hay in feeding value. However, there is often a wastage of 10 to 20 per cent in feeding soybean hay, because of the coarseness of the stems. Taking this into consideration, soybean hay of the usual quality is generally worth only 80 to 90 per cent as much as good alfalfa hay.

SOYBEAN HAY IS A GOOD SUBSTITUTE FOR ALFALFA OR CLOVER

Soybeans are especially useful as an emergency hay crop for dairy cows when alfalfa or clover winterkills. They are also grown regularly for hay by many dairymen.

Later-maturing varieties of soybeans are often grown for hay than are used for soybean production. However, in some experiments the common varieties grown for soybeans have equalled the later-maturing hay varieties in yield and quality of hay produced.[60] For hay, soybeans should be seeded rather thickly, so the stems will not be too coarse.

If the weather is suitable, the crop will make good hay at any stage from the time the pods are formed until the beans are almost fully developed and the lower leaves are yellowing, but be-

fore they drop off. In most tests the largest yields of nutrients have been secured when the crop has not been cut before the seeds were well formed. Also, such late-cut soybean hay, if well-cured, has been equal or superior in value for dairy cattle and beef cattle to earlier-cut hay.[61]

This high value for the late-cut hay, which is coarser and less leafy, is due to the fact that a considerable proportion of such hay consists of soybean seed, rich in protein and fat. Appendix Table I shows that the late-cut hay is richer in protein and total digestible nutrients than hay cut when the seeds are first forming. The condition is thus entirely different than in the case of most kinds of hay, such as alfalfa, clover, or timothy, for generally early-cut hay is richer in protein and more nutritious than late-cut hay.

In deciding when to cut the crop for hay, one must, however, consider the weather fully as much as the composition of the plants. In many sections, especially in the northernmost states, soybeans should be cut before the seeds are well developed in the pods, as the weather late in the fall is apt to be poor for haymaking. Also, when the soybean seeds are nearly full size, but still green, they dry out very slowly in the pods, and are apt to mold when the hay is stored.

Soybeans are more readily cured than cowpeas, but it may take twice as long to cure them well as it does to make alfalfa hay. The best hay is made by curing soybeans in cocks, but if labor is limited, good hay can be made under favorable conditions by the use of the side-delivery rake. Even though soybean hay may be discolored by rains, the hay will usually be palatable to stock. If the soybeans do not contain too much grass or weeds, the crop can be cut with a binder and cured in the shock like small grain.

Combinations of soybeans with Sudan grass, sorghum, or millet are often grown, especially for hay. The combination of soybeans and Sudan grass has proved one of the best late-summer emergency hay and forage crops in the central corn belt. The mixture usually yields more forage than soybeans alone, and it is easier to cure into hay. Such hay has a considerably higher feeding value than hay from Sudan grass alone. In the South a mixture of cowpeas and soybeans cures more easily than cowpeas alone.

486. Soybean hay for dairy cattle.—Numerous experiments have shown that soybean hay is excellent for dairy cattle, but that it is not generally equal to alfalfa, because of the greater wastage.[62] If soybean hay is chopped, cows will eat practically all of it, and such preparation increased its value 19 per cent in Wisconsin trials.[63] However, it must be remembered that the stems are high in fiber and low in digestible nutrients. Probably it would generally be more economical to feed a larger amount of the hay and let the cows leave the stems.

Feeding good soybean hay in place of timothy or mixed hay of ordinary quality makes possible a great saving in the amount of protein supplements needed to balance a dairy ration, and also a saving in the total amount of grain or other concentrates required for high production. For example, in trials at the Minnesota Station feeding soybean hay in place of timothy made possible a saving of 46 per cent in the amount of concentrates fed and nearly eliminated any expenditure for purchased protein supplements.[64]

When soybean hay containing a considerable proportion of soybean seed is fed, along with a concentrate mixture containing ground soybeans, the ration may be too laxative or the cows may tire of the excessive amount of soybeans. This may be avoided by feeding some other roughage in place of part of the soybean hay.

487. Soybean hay for other stock.—Soybean hay is a first-rate substitute for alfalfa or clover hay in feeding *beef cattle.* There has been a considerable range in the results of tests which have been conducted to compare these kinds of hay, probably because soybean hay differs rather widely in value.[65] While the very best quality of soybean hay may

equal alfalfa or clover hay in value, probably average soybean hay is not worth more than about 80 to 90 per cent as much as average alfalfa or red clover hay, because of the greater wastage in feeding it.

Sometimes soybean hay which contains a considerable proportion of beans is unduly laxative for fattening cattle, if they are fed too large amounts. Therefore, the allowance had best be restricted to what they will clean up reasonably well.

For *sheep* soybean hay apparently has some decided limitations for use as the only roughage. It has been satisfactory when thus fed to fattening lambs. However, when pregnant or nursing ewes have been fed soybean hay as the only roughage throughout the winter, the results have occasionally been poor in North Carolina studies.[66] In these instances stiffness of the hind legs, inflamed udders, and difficult lambing occurred in the ewes, and stiffness and spasms in the lambs. Similar trouble has been reported elsewhere.[67] It would therefore seem wise to use soybean hay for ewes only in combination with other roughages, such as corn silage.

For *fattening lambs* soybean hay of good quality, fed as the only roughage, has been worth 83 per cent as much as alfalfa or red clover hay in 8 experiments.[68]

Soybean hay is a good feed for *horses* and *mules* when it is well cured. In Mississippi experiments soybean hay was worth 9 per cent more than Johnson grass hay as the roughage for mules at farm work.[69]

For *swine* soybean hay can be used as a vitamin supplement in the same manner as alfalfa hay, if it is leafy and of first-rate quality. Chopped soybean hay was a satisfactory substitute for alfalfa hay in the trio or Wisconsin supplemental mixture for growing and fattening pigs, and soybean hay has also been used satisfactorily for brood sows.[70]

Similarly, for *poultry* chopped or ground soybean hay can be used as a substitute for alfalfa meal. In Ohio tests with laying hens there was practically no difference in the effectiveness of these feeds.[71] Soybean hay for poultry feeding should be early cut and of good quality.

488. Soybeans and soybean combinations for silage.—Good silage can be made from green soybean forage by using one of the special methods that have been explained in the previous chapter. Making soybeans into silage instead of hay is advantageous where the weather at the time in the fall for harvesting the crop is usually too rainy to make good hay.

A mixture of green soybeans with corn or sorghum forage makes first class silage without the addition of any preservative. The corn and the soybeans may be grown separately and mixed at the time of ensiling at the rate of 1 ton of soybeans with 2 to 4 tons of corn forage, or the corn and soybeans may be grown together.

In some of the experiments in which the mixture of corn and soybeans for silage has been compared with corn alone, the combination has produced a larger yield, while in other tests the reverse has been true. The combination silage will be richer in protein, but it is apt to be a little lower in total digestible nutrients and net energy than well-eared corn silage. This is because the amount of soybean seed produced will usually not quite make up for the reduction in amount of corn grain resulting from growing the combination crop. If the conditions are ideal for corn, the soybeans will be shaded so much that they may not form any important part of the crop. Farmers often greatly over-estimate the weight of soybeans in the forage.

In some of the experiments in which corn-and-soybean silage has been compared with corn silage for dairy cows[72] or fattening cattle,[73] the two kinds of silage have been about equal in value and in other tests the combination silage has been worth slightly more per ton. Apparently, in some cases the higher protein content of the corn-and-soybean silage is counterbalanced by the higher grain content of the corn silage.

When one considers the greater amount of protein in the mixed silage

and also the effects of soybeans on soil fertility (if they are properly inoculated), it seems to be a wise practice to grow soybeans with silage corn, if the yield of forage is not reduced.

Soybeans are also sometimes grown with sorghum for silage. In Mississippi tests the value per ton of sorghum-and-soybean silage for beef cattle was not enough higher than that of sorghum silage, to offset the reduction in yield.[74]

Soybeans are not usually grown alone for silage, because the yield is much lower than of corn or sorghum. In Kentucky trials soybean-molasses silage supplied considerably less digestible nutrients than an equal amount of dry matter in corn or alfalfa-molasses silage.[75] The soybean silage was less valuable than corn or alfalfa silage for wintering ewes. In Florida tests soybean silage was less palatable to dairy cows than corn silage, and about 20 per cent was left uneaten.[76]

489. Soybeans as a soiling crop and for pasture.—Soybeans provide a satisfactory soiling crop for fall feeding, though the green forage is usually less palatable to dairy cows than green corn fodder, green alfalfa, or green clover.

Soybeans are a palatable pasture crop for cattle, sheep, and swine. However, they provide forage for only a rather short season, unless care is taken to remove the stock as soon as most of the leaves are eaten off. If this is done, usually new growth will be made, and the crop can be grazed again in about a month. For pasture, soybeans had best be grown in rows to reduce the loss from trampling the plants. Pasturing should not begin until the plants are well grown.

For swine pasture in the northern states rape, alfalfa, or clover is preferable to soybeans, for these crops provide good feed throughout a much longer season and produce more pork per acre.[77] On the other hand, in some sections of the South soybeans produce larger yields of good forage than any other summer pasture crop suited for swine.[78] In using soybeans for fattening pigs, however, care must be taken to avoid the production of soft pork. This difficulty may be largely prevented by using a late variety of soybeans that will not mature seed until after spring pigs are ready for market.

Well-grown pigs make satisfactory gains when they hog down a field of soybeans after the beans have developed, if they receive a limited amount of corn or other grain in addition.[79] Unfortunately, however, this method of feeding produces soft pork, as is pointed out in Chapter XXXIV. The growing of soybeans in a cornfield that is to be hogged down is discussed elsewhere. (704)

V. Other Legumes for Forage

490. Annual lespedeza.—Annual lespedeza has become the most widely grown legume in the South, both for pasture and for hay. Early varieties of lespedeza are grown as far north as central and northern Illinois and Indiana, but lespedeza has its chief importance in the southern states. Lespedeza is used chiefly for pasture, but 4,000,000 to 6,000,000 acres are usually harvested for hay in this country, with an average yield of about 1 ton per acre. On good soils yields of 2 tons or more may be secured.

Annual lespedeza is especially useful because it is very tolerant to soil acidity, it is drouth resistant, and it will grow on soils too poor for alfalfa or clover. However, liming and fertilizing poor acid soils greatly increases the yield. Another great advantage of annual lespedeza is that it reseeds itself in pastures unless pastured too closely. Thus the stand may be maintained year after year without reseeding. It is therefore exceedingly valuable in permanent pastures, as it adds nitrogen to the soil, helps prevent erosion, and furnishes pasturage well liked by stock. Lespedeza is best maintained in a permanent pasture when grown with a non-sod-forming grass, such as timothy, orchard grass, or tall fescue. Lespedeza rarely causes trouble from bloat. Occasionally, horses slobber on lespedeza pasture.

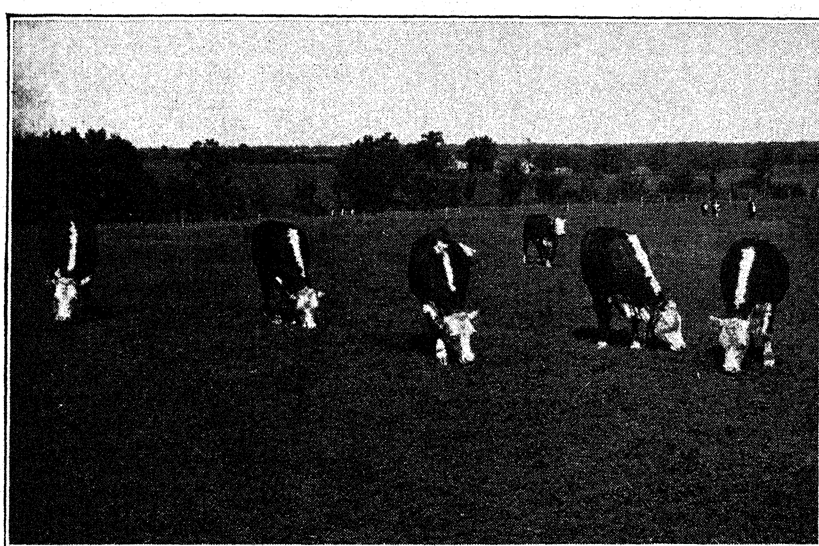
Korean lespedeza (*Lespedeza stipulacea*) is earlier and larger in growth than common lespedeza (*Lespedeza striata*), which is the older type in the

South. Kobe and Tennessee 76 are taller varieties that have been developed from common lespedeza. The forage from all these annual lespedezas has about the same composition and feeding value.

In Missouri a double-cropping system has been developed in which Korean lespedeza follows winter wheat, winter barley, or oats each year.[80] The small grain is grazed or harvested for grain and the lespedeza then comes on and furnishes good pastures or a hay crop.

value. It is of interest that while the stems of most plants contain much more lignin than do the leaves, lespedeza leaves have more of this low-value ingredient and also more tannin than do the stems.[82]

Lespedeza hay cut when in bloom is excellent for all classes of stock, and hay of the best quality may equal or approach good alfalfa hay in feeding value, but is lower in protein, supplying about as much protein as red clover hay.



BEEF CATTLE ON ANNUAL LESPEDEZA PASTURE

The lespedeza volunteered in a crop of oats, and after the oats had been harvested the lespedeza furnished excellent pasture for the rest of the season. (From Etheridge, Missouri Station.)

Lespedeza is fine stemmed and lower in water content than alfalfa, and it therefore is readily cured into hay. It makes much better hay if cut in early to full bloom than when cut later. Experiments have shown that the digestibility of lespedeza hay decreases greatly after bloom, especially when the crop reaches the late seed stage.[81] Late-cut lespedeza hay may be even higher in total protein than early-cut hay, because of the considerable amount of protein-rich seed in the hay. However, it is digested so poorly that it is much lower in digestible nutrients and in feeding

However, the relative value of lespedeza hay, in comparison with alfalfa, has varied considerably in experiments.[83] In some trials it has been fully equal to alfalfa, but in most tests the value has been slightly lower, and in some instances lespedeza hay has been worth only about 80 per cent as much as alfalfa. These differences were probably due to the stage of maturity at which the lespedeza was cut or to the percentage of small grain stubble or other foreign material.

Good-quality lespedeza hay is very satisfactory for dairy cattle, beef cattle,

sheep, horses, and mules. It can also be used in place of alfalfa hay as a vitamin supplement in feeding swine and poultry. In South Carolina tests ground lespedeza hay was even higher than alfalfa leaf meal in carotene, and in Tennessee trials, 5 per cent of lespedeza leaf meal was as satisfactory as alfalfa meal in rations for chicks.[84]

Moldy lespedeza hay may cause a hemorrhagic disease in cattle, similar to the sweet-clover disease.[85] (**480**)

Lespedeza pasture is excellent for dairy cattle, beef cattle, horses, and mules. It does not start growth early in the spring and is killed by hard frosts, and it thus does not furnish pasture over as long a season as does alfalfa or Ladino clover. It is therefore best used in combination with grass or winter grains, which furnish pasture earlier in the spring and also later in the fall.

491. Sericea lespedeza.—In addition to the annual lespedezas, a perennial lespedeza, called sericea lespedeza (*Lespedeza cuneata*) is grown in the southern states for hay, for pasture, and for soil improvement. This perennial lespedeza grows much taller and coarser than the annual varieties, and outyields all other hay crops on poor land.

Unfortunately, ordinary sericea lespedeza is so high in tannin, especially in later stages of growth, that it is unpalatable to stock. If it is cut for hay when not over 10 to 15 inches high, stock will usually eat the hay reasonably well, though there will be some wastage. When cut at this stage of growth, 2 or 3 cuttings of hay can be obtained a year. In cutting the crop, the stubble should be left 2 to 3 inches high, as the new growth comes from the lower part of the stems, and not from the crowns, as with alfalfa or red clover.

Fortunately, a low-tannin variety of sericea lespedeza has recently been developed, which is much more palatable to stock.[86]

The value of ordinary sericea lespedeza hay has varied widely in feeding experiments.[87] In most tests it has been decidedly inferior to annual lespedeza hay or alfalfa hay for dairy cows, beef cattle, or sheep. In a recent Alabama experiment 6-month old dairy calves would eat only half as much sericea hay (cut when 15 inches high and well cured) as they did of early-cut alfalfa hay.[88] They lost weight on the sericea hay and gained well on the alfalfa. Not only was the sericea hay unpalatable, but also only 45 per cent of the dry matter was digested.

When sericea lespedeza is pastured, grazing should begin in the spring when the plants are only 8 to 10 inches high or even less, and enough stock should be pastured in the field to keep the plants from growing up tall and unpalatable.[89] Even then, cattle have sometimes done very poorly on the pasture.

Sericea lespedeza silage has also been less palatable than alfalfa silage or corn silage, and usually worth less per ton.[90]

492. Cowpeas for forage.—The cowpea (*Vigna sinensis*) is a hot-weather annual legume which may be grown from the central part of the corn belt southward. This viny legume, which thrives fairly well on all types of soil, is one of the most important legumes in the cotton belt. Here cowpeas do better than soybeans on the poorer soils, but on the better soils, or even on poor soils when well fertilized, soybeans are usually more productive.

Cowpeas are grown chiefly for forage and for green manure. They also furnish seed for humans and animals, though the seed is usually too high priced for stock feeding. The use of the seed for feeding is discussed later. (**848**)

The common varieties of cowpeas do not mature in a definite time, but continue to put forth new growth and bear pods over a long period. The crop is usually cut for hay when the first pods ripen, but harvesting may be delayed considerably without loss, unless the leaves start to shed. Though the average yield of cowpea hay in this country is only 0.8 ton per acre, the crop will give a yield of 1 ton or more on fertile soil. In the South cowpea hay is frequently called "peavine hay."

Because cowpea hay is rather difficult to cure, it is generally cured in high and narrow cocks, after it has dried out sufficiently in the windrow. Sometimes the hay is cocked about frames or pyramids of poles to permit better air circulation. For hay, cowpeas are often grown with Sudan grass or sorghum to support the vines and to permit easier curing.

Cowpea hay is richer than alfalfa hay in protein and as high in total di-

gestible nutrients. When of good quality, it is equal or nearly equal to alfalfa or clover hay for dairy cattle,[91] beef cattle,[92] sheep,[93] or horses and mules.[94] Well-cured chopped or ground cowpea hay can also be used as a vitamin supplement in feeding swine.[95]

The value of cowpea hay as a source of protein to balance rations is well shown by 3 New Mexico experiments.[96] Steers fattened on a ration of cowpea hay, ground milo grain, and sweet sorghum silage gained as rapidly as others fed cottonseed meal in place of the cowpea hay and sold for just as high an average price. On the average the home-grown cowpea hay was worth 59 per cent as much per ton as cottonseed meal in balancing the ration.

Cowpeas are extensively grown with corn or sorghum, and the crop grazed by cattle, sheep, or pigs. Sometimes more or less of the corn ears or cowpea seed is picked by hand before the stock is turned in. Cowpeas, grown with corn or sorghum, make good silage.

493. Bean forage.—*Field* or *navy beans* (*Phaseolus vulgaris*) are grown for human food instead of for feeding livestock, but the cull beans, discolored or otherwise unsuited for human consumption, are fed to livestock, and also the bean straw, commonly called "bean pods." The use of cull beans and bean straw is discussed on other pages. (844, 513)

Mung beans (*Phaseolus aureus*) have proven to be a good annual hay crop for certain sections of the southern plains. Mung beans resemble cowpeas in growth, but are coarser and less viny. They produce fair yields on poor soils where alfalfa will not thrive and are generally not injured by disease or insects. The green variety is finer stemmed than golden mung beans and yields considerably less forage, but more seed. The use of the seed for feeding is discussed later. (844)

Mung beans should be cut for hay when the pods are well developed, but when only a few have turned brown. Curing had best be finished in cocks, as the forage cures slowly. In Oklahoma tests mung-bean hay was very satisfactory for dairy cows, but on account of the stemmy nature there was more wastage than of alfalfa hay.[97] Golden mung-bean hay, as fed, was worth nearly as much as alfalfa hay per ton, while green mung-bean hay was of slightly lower value. In an Arkansas trial chopped mung-bean hay equalled alfalfa hay for dairy heifers.[98]

In the Oklahoma tests mung beans made satisfactory silage without any preservative, and the silage did not have a strong odor. It required 285 lbs. of mung-bean silage to equal 100 lbs. of alfalfa hay in value.

In certain sections of the Southwest, *tepary beans* (*Phaseolus acutifolius*) are a better hay crop than soybeans or cowpeas, as they are more resistant to drouth and heat. Tepary-bean hay equalled alfalfa or cowpea hay for dairy cows and heifers in Oklahoma tests.[99]

Sometimes silage is made from *green lima bean* vines or *snap bean vines*, after the green beans are removed. The palatability and value of such silage apparently differs widely, depending on how green the leaves were and on how the silage is made. Lima bean silage of good quality was satisfactory for dairy cows in Delaware experiments, though less palatable and somewhat less valuable than corn silage.[100]

Dehydrated bean vine meal, made from green snap bean vines after the beans were picked, compared favorably with alfalfa meal as a vitamin supplement for chicks in a Florida test.[101] Meal made from vines after the leaves had matured was decidedly inferior.

494. Birdsfoot trefoil; big trefoil.—*Birdsfoot trefoil* has recently become important in some of the northern states as a promising perennial pasture and hay legume. When once well established, it will endure many years in pasture or hay mixtures, for it is very winter hardy. It will grow on land too poor or too sour for alfalfa. Also, it is suited to a wide range of soils, it is more drouth tolerant than white or red clover, and it will stand a moderate amount of alkali. Birdsfoot trefoil has not been known to cause bloat. In composition and feeding value, the hay compares favorably with alfalfa, and the pasture with white clover.[102] Two cuttings of hay can be made a year. Where alfalfa, red clover, or Ladino clover thrive, they outyield birdsfoot trefoil.

Broad-leaved birdsfoot trefoil (*Lotus corniculatus*), the kind most commonly grown, is best adapted to dryer and less fertile soils. It is deep rooted and stands drouth very well. The narrow-leaved birdsfoot trefoil (*Lotus tenuis*) is adapted to moist and fertile soils and is less drouth resistant. In most areas it is inferior to the broad-leaved kinds.

Unfortunately, birdsfoot trefoil becomes established slowly, and the yield is low the year after seeding. Also, it is sometimes diffi-

cult to secure a satisfactory stand. There are two types of broad-leaved birdsfoot trefoil, the Empire variety selected by the New York (Cornell) Station from plants that had persisted for many years on hill land in eastern New York, and the European strains. The latter are more erect in growth, have greater seedling vigor, and recover more quickly after cutting. However, they apparently do not persist so long in pastures. Viking, Granger, and Cascade are varieties of this type.

In many of the northern states from New England to the Midwest, birdsfoot trefoil has given excellent results, being considered the most promising legume for permanent pastures or hay fields.[103] In other states the results have not been favorable.[104] Since birdsfoot trefoil is slow to become established, it should not be used in short crop rotations.

For hay, birdsfoot trefoil should be seeded with a strong-stemmed grass, such as timothy, orchard grass, or brome grass, to support the weak stems and prevent lodging. For pasture, it should be seeded with one of these grasses or with Kentucky bluegrass.

Big trefoil, or marsh trefoil (*Lotus uliginosus*), which is grown but little in this country and which is not winter hardy, grows on wet land, even on marsh land.[105]

495. Crotalaria.—Crotalaria, an annual legume, is grown in the southern states, especially in Florida, for green manure. The kind grown most commonly for this purpose is *Crotalaria spectabilis.* This and some other species are poisonous to livestock, the seed being especially toxic.[106] Many animals have been killed by grazing these crotalarias.

Crotalaria intermedia and certain other species, on the other hand, are entirely harmless. *Crotalaria intermedia* produces a high yield of forage, but the pasture is not very palatable and cattle have to learn to eat it.[107] The plants produce a considerable proportion of hard seed, and it volunteers in pastures. The crop makes satisfactory silage, but the hay is apt to be stemmy and unpalatable.

496. Desmodium; Kaimi clover.—*Beggarweed,* or tall tick clover (*Desmodium tortuosum*), is an annual legume which has rather woody stalks 3 to 10 feet high bearing abundant leafage. This and other desmodiums are used for green forage and hay production in subtropical regions.[108] Beggarweed does well on sandy land. It should be cut for hay at the beginning of bloom, before it becomes too coarse and woody or the lower leaves drop off. Such hay is relished by stock, but the greatest value of the crop is for grazing.

In tests in Guatemala meal made from another desmodium (*Desmodium intortum*) was a satisfactory substitute for alfalfa meal in chick rations.[109]

In Hawaii *Kaimi clover* (*Desmodium canum*) is becoming the most important grazing legume in humid lowland pastures.[110]

497. Flat pea.—The flat pea (*Lathyrus sylvestris*) is a perennial legume that shows promise of meeting the need for a pasture plant which will produce a satisfactory yield on logged-off land in the northern Pacific Coast states, and which will compete with bracken fern and underbrush and not dry up in midsummer on hilly land.[111] The forage is exceedingly rich in protein, having 20 per cent or more of digestible protein on the dry basis, and also is high in total digestible nutrients. Unfortunately, the seed is poisonous to stock when they consume too large amounts. There may therefore be some danger in pasturing flat peas when much seed has formed.

498. Guar.—Guar (*Cyamopsis tetragonoloba*) is a coarse, upright annual legume grown in India for seed for human consumption and for forage. In Texas tests stock, except sheep, refused to graze guar, because of the very hairy, nettling leaves.[112] If the forage was cut and wilted, it was eaten readily.

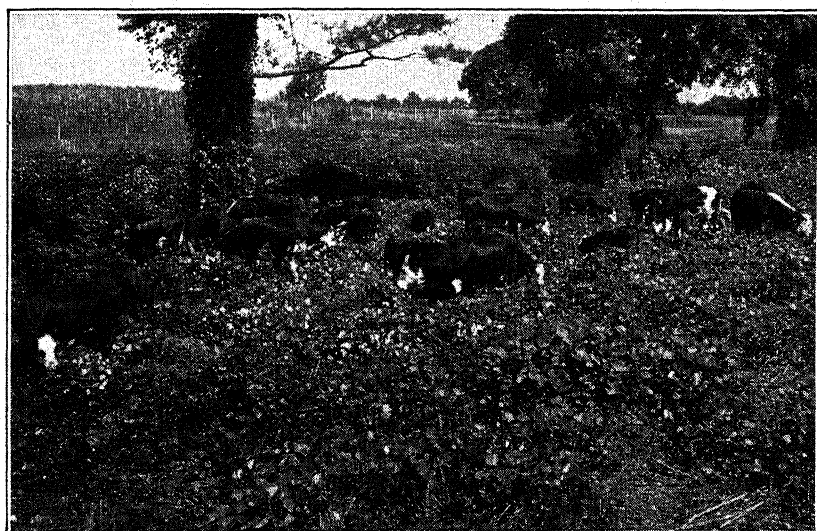
499. Indigo.—Hairy indigo (*Indigofera hirsuta*) is a coarse-growing annual summer legume sometimes used for pasture or hay in Florida and the southern Coastal Plain. It reseeds itself in pastures unless grazed too closely. Hairy indigo grows fairly well on rather poor sandy land and has a low lime requirement. Sensitive to cold, it is killed by the first frost.

Good results have been secured at the Florida Range Cattle Station when hairy indigo-grass pasture has been used in combination with other pasture.[113] When grazed continuously on hairy indigo alone, it produced lameness in some animals, apparently due to some toxic effect. It should therefore be seeded in combination with grass.

Creeping indigo (*Indigofera endecaphylla*) is a promising annual legume to be used in combination with grasses in high rainfall areas of the Hawaiian Islands.[114] Unfortunately, if it forms over half of the forage it has a toxic effect on cattle and sheep. Creeping indigo meal produced satisfactory results when it formed not more than 2.5 per cent of a ration for growing chickens, but 5 per cent depressed growth.

500. Koa haole.—Koa haole (*Leucaena glauca*), a shrubby perennial legume, is grown extensively on drier range land in Hawaii.[115] If it forms too large a part of the feed for horses, swine, chickens, or rabbits, it may cause illness. However, dairy cows have been fed koa haole soilage as the only roughage for more than 3 years without injury. Feeding the kao haole, which is rich in protein, made unnecessary the purchase of expensive protein supplements. However, it yielded only about one-third as much forage per acre as Napier grass.

Kudzu usually forms but little seed and the seed does not germinate well under field conditions. The crop is therefore propagated by setting out crowns, vine cuttings, or seedlings. It requires from 1 to 5 years to become fully established, but it then persists long under proper management. It will not stand close, continuous grazing, but may be pastured moderately until early fall. The stock should then be taken off, so that a new crop of leaves can be put forth and the food reserves built up in the roots, before freezing weather kills the leaves. Otherwise, it is apt



Beef Cattle on Kudzu Pasture

In the southern states kudzu prevents erosion on hilly land and furnishes a high yield of good pasturage or hay. It supplies an abundance of feed in midsummer, when permanent pastures are commonly poor. (From Mississippi Station.)

to winterkill. After the leaves have died, kudzu will furnish a month's grazing without injury to the stand.

Koa haole meal or fresh leaves satisfactorily replaced alfalfa meal in rations for laying hens and for chicks.

501. Kudzu.—Kudzu (*Pueraria thunbergiana*) is a rapid-growing perennial legume vine that has become very important during recent years in the southern states. Here it prevents soil erosion on hilly land and furnishes a high yield of good pasturage or hay. The viny branches grow many feet along the ground, rooting at the joints and forming new crowns, from which twining shoots 2 to 4 feet high are sent up. These may be cut with a mower without great difficulty, particularly with a special device on the cutter bar to separate the cut and uncut forage.

Kudzu furnishes excellent legume pasture from late spring all through the summer, supplying an abundance of feed in midsummer, when permanent pastures are usually poor. In experiments it has been satisfactory for dairy cattle,[116] beef cattle,[117] swine,[118] and poultry.[119] Pigs will somewhat more than maintain their weights on kudzu pasture alone, without grain, and may thus be carried along to be fattened in the fall on a crop of corn or peanuts. When fed grain, without any protein supplement, on kudzu pasture pigs make good gains. Kudzu is also a good grazing crop for poultry.

Kudzu should not be cut for hay until it is well established, and then not more than 2 cuttings a year should be made, or else the stand will be injured. Kudzu cures into hay rather easily, and the hay is about as rich as alfalfa in protein. Good-quality kudzu hay has given good results with dairy cattle, beef cows, or fattening cattle.[120] It is too coarse and stemmy for calves. Kudzu can also be made into silage.[121] Dehydrated kudzu meal or leaf meal is a good substitute for alfalfa meal for poultry or swine.[122]

Ordinary kudzu does not do well in the tropics, but *tropical kudzu* (*Pueraria phaseoloides*), a close relative, fills a need for a vigorous, perennial legume which covers the ground quickly from seed.[123] It is relatively resistant to drouth, grows well in moderate shade, has no serious diseases or pests, and makes good pasture. It is a common crop in Java, Sumatra, and Malay and is proving well adapted to Puerto Rico.

502. Lupines. Lupines (*Lupinus* spp.) are grown in the Gulf Coast states as an annual winter crop, and in some localities produce more green material than any other winter legume.[124] The varieties generally grown in the South as a cover crop are poisonous to stock, but sweet lupine varieties have been developed which make good pasture. However, some of the seed sold as sweet lupine contains considerable of the bitter, toxic kind.

503. Peas for forage; peas and oats.—Field peas (*Pisum arvense*), the use of which as a grain crop is discussed in Chapter XXII, are grown in Canada and the northern states to some extent for forage. They do not thrive where the season is hot. A combination of peas and oats, if cut early and well cured, makes hay which is slightly richer than red clover hay in protein, but usually not so palatable. In trials with fattening lambs oat-and-pea hay has been decidedly inferior to alfalfa hay, being worth only about three-fourths as much per ton.[125]

Peas and oats make satisfactory silage, if not ensiled until the oats are in the dough stage and the peas have hardened. Such silage is not quite equal to corn silage but is useful north of the corn belt, especially as an emergency silage crop when alfalfa or clovers winterkill.[126]

Peas and oats are sometimes sown as a spring soiling crop, especially for dairy cows, and are one of the best early annual crops for this purpose.

Peas and oats are sometimes used as pasture, especially for swine. However, the crop does not furnish pasturage over a very long season, and stock may tramp down and waste considerable of the forage. For pasture this mixture is therefore excelled by rape or by a combination of oats, peas, and rape.[127] By sowing rape with peas and oats, pasture may be provided until late fall if conditions are favorable, for the rape will come on after the peas and oats are grazed off.

Austrian winter peas are sometimes grown in combination with winter oats or other winter grain for winter and early spring pasture in the southern states and in certain sections of the Pacific Coast district. Occasionally, a peculiar lameness occurs in pigs on Austrian winter peas, apparently due to some injurious substance in the peas.[128]

504. Lambing or hogging down field peas.—In certain localities of the West, field peas, usually sown with a small amount of oats or barley to support the vines, are sometimes grown for lambing down by fattening lambs or for hogging down when the crop is nearly mature. Unfortunately, serious death losses from "overeating disease" frequently occur among lambs grazed on field peas. The method is therefore used much less than formerly.[129]

Fairly good gains are made by pigs hogging down peas, if the vines are still green. In North Dakota tests 385 lbs. of pork were produced per acre of peas hogged down, and in Idaho tests 406 lbs.[130] More rapid gains are made when the pigs are fed a limited amount of grain in addition to the peas, and the results may be still better when a small amount of high-quality protein supplement, such as tankage or meat scrap, is also fed.

505. Pea-cannery waste; pea-vine silage.—*Pea-cannery waste* consists of the pea vines and empty pods, left after the green peas are removed at the pea-canning factories. It is usually put in large stacks, where the decaying outside layer preserves the mass of silage within, or else it is put in silos. No preservative is needed, because the peavines are rich in sugar.

The *pea-vine silage* has a strong odor, but is an excellent feed for dairy cows, cattle, and sheep. It contains considerably more digestible protein than corn silage, but it supplies less total digestible nutrients. The silage is rich in carotene. Where advantage can be taken of its richness in protein by saving on protein supplements that would otherwise be needed to balance the ration, pea-vine silage is worth 90 per cent as much as well-eared corn silage per ton. If fed in a ration

that contains more protein than needed, pea-vine silage is probably worth only about 75 to 85 per cent as much as well-eared corn silage.[131]

Though pea-vine silage has a strong odor, it does not injure the flavor of milk, if fed after milking in a well-ventilated barn and if spoiled portions are discarded. For fattening cattle or lambs, pea-vine silage gives the best results when fed with some hay.

Dehydrated pea vines were a good substitute for alfalfa meal as a vitamin supplement for chicks in a Maryland test and for pigs in a Washington trial.[132]

506. Peanuts for forage.—Peanuts (*Arachis hypogea*) are grown chiefly for the underground nuts. However, when peanuts are raised for market, the forage is a valuable by-product. The peanuts are usually harvested with a digger which cuts off the lower roots and lifts the plants with the nuts attached.

A common method of curing the crop is to stack the plants, after the leaves have wilted somewhat, about stakes set in the ground, with cross pieces on them to keep the plants off the ground. After curing for 3 to 6 weeks, the nuts are picked from the vines by a threshing machine, leaving as a by-product the cured forage, usually called "peanut hay" instead of "peanut straw."

Such peanut hay, if well cured, leafy, and not moldy, is of much higher value than one might estimate from its appearance, and it is so palatable to stock that it is eaten with surprisingly little waste. Good-quality threshed peanut hay is lower in protein than alfalfa or soybean hay. However, it is higher than these hays in nitrogen-free extract and lower in fiber, even though it has all of the stems and also some roots. Peanut hay practically always contains some dirt or other foreign material. Therefore, it is a good plan to shake the dirt from the hay or to feed it in a rack, so the stock can refuse the coarsest stems, if they wish, and so any dirt will fall out.

The average yield of threshed peanut hay is about one-half ton per acre, and usually more than a ton of hay is secured for each ton of unhulled peanuts.

Sometimes the peanut plants are cured in windrows, a side delivery rake being used to turn the vines at intervals of several days. Unless the weather is very favorable, most of the threshed hay obtained by this method is badly discolored, very stemmy, dirty, and rather unpalatable. Low-grade peanut hay may not be much higher than small-grain straw in feeding value. Moldy peanut hay or that which carries much dirt or dust is not suitable for horses or mules, as it may cause digestive trouble.

In experiments in which threshed peanut hay has been fed to dairy cattle,[133] to beef cattle[134] and to sheep[135] the results have differed greatly, undoubtedly depending on the quality of the peanut hay. In some of the trials peanut hay has been nearly equal to good alfalfa, lespedeza, or cowpea hay. However, in other tests the peanut hay has been much lower in value.

The residue from dusting the growing peanut vines with sulfur or copper-sulfur fungicide to control disease has not injured stock fed such hay.[136]

The hogging down of peanuts is discussed later. (839) When peanuts are grown for this purpose, the peanut vines are sometimes mowed and cured into hay before the hogs are turned in. Such hay is fully equal to alfalfa or lespedeza hay in value.

The entire cured peanut plants, including nuts, also make a first-rate feed. In North Carolina tests, when ground peanut plants, including nuts, formed half the concentrate mixture for dairy cows, the milk production was as good as with a concentrate mixture made up of ground corn, ground oats, cottonseed meal, and wheat bran.[137] Good results were likewise secured when peanuts and vines were fed to dairy cows or fattening cattle in other tests.[138]

507. Pigeon pea.—The pigeon pea (*Cajanus cajan*) is a legume shrub which is grown in the tropics for its edible seed. In Hawaii it was raised extensively as a grazing crop for beef cattle, and as a protein-rich soiling crop for dairy cows. However, the acreage has declined greatly, because it yields much less forage per acre than Napier grass, and because it is short lived.[139]

508. Serradella.—Serradella (*Ornithopus sativus*) is cultivated to some extent in Europe on poor sandy land, as it will grow on soil too acid for most legumes. Though it has often been tested in the United States, it has proven inferior to other crops, even on acid, sandy soils.

509. Singletary peas.—Singletary peas (*Lathyrus hirsutus*), also called Caley peas, rough peas, or wild winter peas, are used in the Gulf Coast states to some extent for supplementary grazing in late winter and early spring.[140] The singletary pea is a viny annual winter legume, resembling vetch. The seed is poisonous to stock, and the crop should not be pastured after pods have formed. An

advantage of singletary peas is that they produce much more seed per acre than such legumes as vetch, and the seed is therefore cheaper.

510. Velvet beans.—Velvet beans (*Stizolobium*, spp.) are vine-like annual legumes grown throughout the cotton belt, except in the extreme northern part. They grow well on poor, sandy soil and on soil deficient in lime, provided it is well drained. Even the early varieties make a tangled mass of vines 3 to 10 feet long, while the later ones may run to 30 feet or more.

Velvet beans are difficult to cure into hay, and over 90 per cent of the acreage is grown in combination with corn to support the vines. The crop is commonly used for grazing, after most of the ears of corn and perhaps some of the ripe beans have been picked by hand. On sandy soil the leaves, vines, and pods do not decay readily after they are killed by frost, and the crop often furnishes feed until early spring.

Velvet beans furnish good pasture for cattle and sheep, but not for swine.[141] With fattening pigs the gains are usually satisfactory as long as the corn lasts, but then they are often poor.[142] This is because velvet bean seed is unsatisfactory for swine when forming any considerable part of the ration. (856)

Silage may be made from the combination of velvet beans and corn. Though it has a very dark color, it is eaten readily by stock.

The use and value of velvet-bean seed, of velvet beans in the pod, and of velvet-bean feed are discussed in Chapter XXII.

511. Yellow trefoil, or black medic.—Yellow trefoil, or black medic (*Medicago lupulina*), a relative of alfalfa, is a creeping legume, usually an annual, which is somewhat like white clover in habit of growth. It is commonly not prominent in permanent pastures, except on the black prairie soils of Alabama and Mississippi, where it occasionally furnishes a considerable part of the pasturage in early spring. Because of its small size, yellow trefoil is less productive than other legumes that may be grown.

512. Vetch.—The vetches raised in the United States are grown chiefly as winter annuals for hay, for pasture, or for soil improvement in the extreme southern states and in the northern Pacific Coast region, where the winters are not severe. Vetch is also grown in some of the northern states, especially on sandy soils, being seeded either early in the spring or in the fall. Vetch is a cool-weather crop and does not thrive in summer in the central states.

For hay, vetch is usually sown with small grain to support the weak vines, which may clamber 4 or 5 feet or more in a tangled mass. The hay is easy to cure but somewhat difficult to handle because of its tangled nature. Pure vetch hay is about equal to clover hay in value, and yields of 2 tons or more per acre are secured under favorable conditions. The value of oats-and-vetch hay will depend somewhat on the proportion of vetch. In Oregon tests oats-and-vetch hay was not satisfactory as the only roughage for fattening lambs.[143]

The vetches also furnish excellent pasture for stock, the crop sometimes being pastured when young and then being allowed to grow up for hay or seed. In a Mississippi test dairy cows grazed on vetch-and-oats pasture in winter produced decidedly more milk than others kept on permanent pasture.[144]

The combination of vetch and oats also makes good silage. In the coast sections of Oregon and Washington this combination is often sown in the fall and ensiled in early summer. In Oregon trials the average yield of vetch and oats for silage was 16 tons per acre, which was double that of corn.[145] The vetch-and-oats silage was as palatable as corn silage and equalled it in feeding value. In Canadian trials oats-vetch-and-pea silage was slightly inferior to corn silage for milk production.[146]

The two kinds of vetch most commonly grown in the United States are hairy or winter vetch (*Vicia villosa*), also called sand vetch, and common vetch (*Vicia sativa*). Both are ordinarily annuals, although hairy vetch may behave as a biennial when seeded in the spring. Hairy vetch is more winter hardy and more drouth resistant than common vetch, and may be grown on poorer soils. Other kinds of vetch grown to a lesser extent are Hungarian vetch, Monantha vetch, and purple vetch. Vetches are sometimes called tares.

513. Legume straw or chaff.—The straw or chaff that is left after ripe leg-

umes are threshed for seed is often used for stock feeding. Legume straw contains much less protein than hay made from the same crops and is much higher in fiber and therefore lower in total digestible nutrients. If the legume straw contains a considerable proportion of leaves, the protein content will be decidedly higher than that of straw from the small grains.

The value of legume straw or chaff varies widely, depending chiefly on the proportion of leaves and the manner in which it was cured. It can be fed satisfactorily as part of the roughage to dairy cattle, beef cattle, or sheep, but it is often too dusty for feeding to horses. Legume straw gives much better results when it is fed as only part of the roughage, along with good legume hay or else with silage, than when it is the only roughage.

Alfalfa or clover straw, when well cured, is of greater value than straw from the coarser legumes, such as soybeans or field beans. In an Idaho trial alfalfa or clover straw was worth about one-half as much as alfalfa hay when it replaced part of the hay in a ration for fattening lambs.[147] On the other hand, when alfalfa or clover straw has been fed as the only roughage or the chief roughage to fattening lambs or the breeding flock, the results have usually been unsatisfactory.[148]

Bean straw from field or kidney beans, often called "bean pods," is used for feeding cattle, sheep, and horses in the bean-growing districts. Its value varies widely, but when of good quality it is satisfactory as part of the roughage when fed with good hay. Thus fed, it is worth about as much as corn or sorghum fodder, or one-half as much per ton as alfalfa or clover hay.[149]

Lespedeza straw of excellent quality, cured without exposure to rain and containing a high proportion of leaves, was a satisfactory substitute for good soybean hay in an Illinois trial with dairy cows, when both were fed with corn silage and a suitable concentrate mixture.[150] Though the lespedeza straw did not seem so palatable as the soybean hay, the cows actually wasted a smaller percentage of it.

Pea straw from field peas varies widely in value, and straw from combine threshing is worth less than that from a stationary thresher, as the pea vines are usually more mature when the crop is harvested and the straw has less leaves. Pea straw had best be fed as not over half the roughage, along with good legume hay or silage.[151] Thus fed, its value will range from less than half to three-fourths that of alfalfa hay.

Soybean straw usually consists chiefly of the coarse stems with a very small proportion of leaves, and it therefore has a low feeding value. It should be fed as only part of the roughage, preferably along with some good legume hay. Also, it had best be used for animals that are not being fed for high production. For example, it is more satisfactory for dry cows or for heifers than for cows in milk.[152] When fed as the only roughage for fattening lambs in an Illinois trial, soybean straw gave poor results, even though sufficient protein supplement was fed to balance the ration.[153] The straw, which had only 3.4 per cent protein, was worth but one-fourth as much as alfalfa hay. The soybean crop had a much higher value as hay than when fed as soybean straw plus soybean seed.

QUESTIONS

1. State 9 advantages of legume forages.
2. Why should livestock farmers grow a large acreage of alfalfa wherever the soil and climate are adapted to the crop?
3. What varieties of alfalfa are best suited to your section? Why?
4. Discuss the effect of various factors on the composition and value of alfalfa hay.
5. What effect does the stage of maturity at which alfalfa is cut for hay have on its longevity?
6. What are *alfalfa meal, alfalfa leaf meal,* and *alfalfa stem meal?*
7. Discuss the value and use of alfalfa hay for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses; (e) swine; (f) poultry.
8. What is the relative value of alfalfa meal

when added to the concentrate mixture for dairy cows fed plenty of good roughage?
9. Discuss the use of alfalfa for pasture.
10. Discuss the use of alfalfa for silage; as a soiling crop.
11. Why are alfalfa-grass mixtures preferable to pure alfalfa in many regions?
12. Compare the merits of red clover and alfalfa as hay crops for your locality.
13. At what stage of maturity should red clover be cut for hay?
14. Discuss the use of red clover for pasture; for silage; as a soiling crop.
15. Of what importance are the following in your locality: (a) Mammoth clover; (b) alsike clover; (c) white clover; (e) Ladino clover; (f) crimson clover?
16. Discuss the use of sweet clover for pasture and for hay.
17. What other clovers are grown in your area?
18. What is the value of soybean hay for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry?
19. Should soybeans or soybean combinations be raised for silage in your area?
20. Discuss the use of soybeans as a soiling crop and for pasture.
21. Discuss the value as forage crops of any of the following that are important in your state: (a) Annual lespedeza; (b) sericea lespedeza; (c) cowpeas.
22. Which of the other legumes discussed in this chapter are grown in your state, and how are they used?
23. How can legume straw or chaff be used best in stock feeding?

CHAPTER XVII

INDIAN CORN AND THE SORGHUMS FOR FORAGE

I. Indian Corn

514. Indian corn excels as a forage crop.—Indian corn (*Zea mays*) is well called king among our crops in the United States, for corn far excels other crops both in acreage and in value. Our corn is raised chiefly for grain, but it is also our main silage crop, and a large acreage is grown for hogging down, for fodder, or for grazing. When corn is grown for grain, the stover left after husking can be an important winter feed for stock.

With the acreage restrictions that have been in force, the acreage of corn harvested in the country has recently been about 80,000,000 acres. Over 85 per cent of our corn is grown for grain, only 7 to 8 per cent being raised for silage and 4 to 5 per cent for hogging down, fodder, or grazing.

When the entire corn plant is used for forage, as in growing it for silage, it excels all other forage crops in average yield of dry matter and of digestible nutrients per acre. In these respects it even slightly surpasses alfalfa, the queen of the legume roughages. (**450**)

Though it flourishes best in the corn belt, corn is an exceedingly adaptable crop, and it is raised for grain or for forage on more than two-thirds of all the farms in the United States. Corn is a heat-loving plant and does not thrive if the nights are cool. However, early-maturing, short varieties have been developed that will usually ripen in the northern-most states.

If corn is planted rather thickly, a heavy yield of forage is secured, with but little grain. On the other hand, when the plants are grown the proper distance apart, there is a large yield of grain, with forage as a secondary product. As is pointed out later in the discussion of corn as a grain, it ranks first among the cereals in feeding value and also in yield of grain per acre. (**681**) In addition, the corn stover is worth much more per acre for stock feeding than the straw from the small grains.

515. Corn fodder; shock corn; corn stover.—In discussing the uses of corn as a forage crop, it is important to have definitely in mind just what is meant by the terms used in speaking of corn forage.

The terms *corn fodder* and *fodder corn* are commonly used for corn plants, either fresh or cured, which have been grown primarily for forage, with all of the ears, if any, originally produced. *Shock corn* (sometimes called bundle corn) means corn grown primarily for grain, but which is fed without husking. Sometimes shock corn is also called corn fodder.

Corn stover is the term applied to cured shock corn from which the ears have been removed. Corn stover is often called "corn stalks," but this term is misleading, for the greater feeding value is in the leaves and not in the stalks.

The terms fodder and stover are also applied to such crops as the sorghums. For example, kafir forage is called either kafir fodder or else kafir stover, depending on whether or not the heads have been removed.

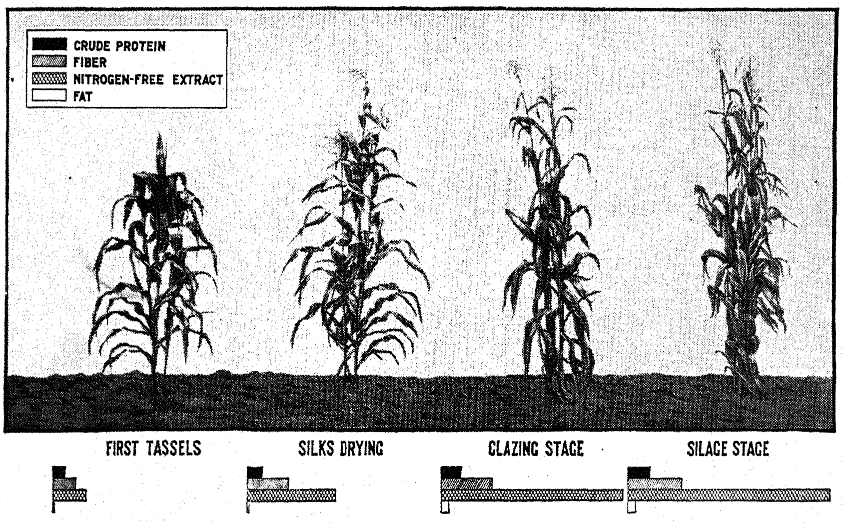
516. Thickness of planting.—The greatest yield of sound corn grain is secured when the kernels are planted far enough apart so all the plants produce full-sized ears. A common rate for dent corn on good soil in the corn belt was formerly 10,000 to 12,000 kernels per acre. In recent tests hybrid corn has yielded best on well-fertilized soil with as many as 16,000 plants per acre. On less fertile soil or where rainfall is scanty,

the rate should be less. Early-maturing, short varieties should be planted somewhat more thickly than larger varieties.

Under favorable conditions the largest yields of total dry matter and of digestible nutrients are secured from corn planted more thickly than when grown for grain, but the yield of grain will then be much less. If the crop is raised for silage to be fed to stock that need a liberal allowance of concentrates (such as milk cows or fattening cattle or sheep), it is best to plant it at a rate which will produce a large proportion of ears. However, the crop even then is usually planted a little more thickly than when it is raised for grain.

If the silage is to be fed to beef breeding cows not nursing calves or to yearling or older beef cattle which are being carried through the winter to be fattened on grass the following summer, sometimes the corn is planted so thickly that the proportion of ears is small. This is because such cattle do not need much grain. Another method occasionally used for such stock is to feed corn-stover silage, or to husk out some of the ear corn before the crop is ensiled.

517. Nutrients lost when crop is harvested too early.—Experiments in which corn plants have been analyzed at various stages of growth have shown that there is a heavy loss of nutrients when the crop is harvested too early. At the milk stage, when corn is sometimes cut for silage, the crop has the greatest green weight. However, an acre of corn then has only two-thirds as much dry matter as when the kernels have ripened. There is even greater difference in the amount of total digestible nutrients or of net energy per acre, because of the great storage of starch in the corn kernels as they mature.



NUTRIENTS IN CORN PLANTS AT VARIOUS STAGES

The shaded areas in the legend represent the amounts of crude protein, fiber, nitrogen-free extract, and fat in corn plants at various stages. Note especially the large storage of nitrogen-free extract as the crop matures. (From Indiana Station.)

In Indiana experiments it was found that from the milk stage to the date when the corn was ready to shock (a period of less than a month), there was a gain per acre of 2,500 lbs. nitrogen-free extract, over a ton of which was starch.[1] Nearly all of this storage had taken place by the silage stage, when the kernels were dented.

The chief storage of fat also occurs after the milk stage, when the germs in the kernels are developing. On the other hand, the increase in protein, fiber, and

mineral matter is most rapid in the earlier stages, when the leaves and stalks are growing fastest.

518. Composition of corn forage.—Like corn grain, corn forage is high in carbohydrates and low in protein. Well-dried corn fodder has only about half as much protein as does alfalfa hay, and corn stover has even less.

When the corn crop is stricken with drouth, so that no ears develop and the plants are killed, the forage will have a considerably higher percentage of protein than normal, but the total yield of nutrients will be low. Likewise, corn harvested in the milk stage or before will contain a higher percentage of protein, on the dry basis, than more mature forage. However, such immature forage is watery and low in total nutrients.

Corn forage resembles grass hay in content of both calcium and phosphorus. Corn fodder or silage grown on soil well supplied with calcium is fair in calcium content, having 0.25 per cent or more on the dry basis. Corn stover is higher than corn fodder in calcium. Where the soil is deficient in calcium, the corn forage will be low in this mineral.

Corn fodder and corn silage are rather low in phosphorus. The percentage depends somewhat on the phosphorus supply in the soil, and corn forage grown on phosphorus-poor land will be deficient in this mineral. Corn stover is very low in phosphorus, as most of the phosphorus is in the grain.

Green corn forage, even from white corn, is high in vitamin A value. This is because the green corn leaves and stalks contain a greater total amount of carotene than the grain, even in the case of yellow corn. The vitamin A value of dry corn fodder will vary widely, depending on whether the leaves and stalks were green when the crop was harvested, and on how well it was cured.

Differing from most other green, growing crops, green corn forage may supply considerable vitamin D, if not harvested before the dent stage. Michigan studies, mentioned previously, show that the leaves which are still green have practically no vitamin D, but the dried parts—tassels, silks, husks, and any dried leaves—are rich in the vitamin. (**204**) Corn silage harvested at this stage therefore furnishes much more vitamin D than does hay-crop silage, which may have little or none. In the Michigan investigation corn silage supplied sufficient vitamin D to meet the needs of dairy cows or of yearling heifers.[2]

Even when grown for grain, an appreciable part of the feeding value of the corn crop is in the stover.[3] The stover will have nearly one-half of the dry matter and about one-fourth of the digestible protein and net energy of the entire crop. This shows the loss of feeding value that occurs when corn stover is not utilized.

519. Corn silage.—Wherever corn thrives, it is an ideal silage crop. For this reason, by far the greater part of all the silage in this country is made from corn. If green corn forage is harvested at the proper stage of growth and is ensiled with ordinary care, it almost always makes excellent silage. The cut forage packs well in the silo, and it contains sufficient sugar so that enough acid is produced in the silage to keep it from spoiling. (**425**)

The fact that corn almost invariably makes good silage is an important point to consider in deciding whether to use corn or hay crops, such as alfalfa, for silage. Good silage can generally be made from hay crops, if care is taken to use one of the special methods which have been described earlier. (**428–435**) However, sometimes the hay-crop silage is decidedly inferior in quality to the usual grade of corn silage.

The yield of silage per acre varies widely with the soil and season. A 50-bushel crop of corn should make from 8 to 10 tons of silage, depending on the size and leafiness of the plants. The average yield of corn grown for silage in this country is about 8 tons per acre, but 10 tons or more are readily secured when the crop is grown on fertile land well adapted to corn.

Corn makes the best silage if cut when the kernels have reached the glazing stage, but while most of the leaves

are still green. At the glazing stage the dent varieties will be well dented. Ensiling the corn should not be delayed longer, or the corn will become too mature to make the most palatable silage, and it may mold unless water is added as the cut forage is ensiled. On the other hand, if ensiled too early, very sour silage is produced. Still more important, there is a great waste of nutrients, for the chief storage of starch will not have occurred.

The vitamin A value of the silage is much lower if the crop is ensiled when the leaves have begun to turn yellow. In a Wisconsin test early-dent-stage corn silage had 3 times as much carotene as late-harvested silage.[4] When cows were changed from the more mature silage to that made at the early-dent stage, the vitamin A content of their milk was doubled.

The leaves of many of the hybrid corn varieties stay green longer than those of the old open-pollinated varieties. Therefore the best way to tell when hybrid corn is ready for the silo is to examine the ears, or the crop may get too mature for the best silage before one is aware of it.

It has been pointed out previously in this chapter that corn silage harvested at the dent stage may supply enough vitamin D to meet the needs of dairy cows and yearling heifers. (518) It thus differs greatly in this respect from most hay-crop silage.

Although hybrid corn generally has stiffer stalks than many of the old varieties, it is more leafy and has no more fiber and no more lignin (the least valuable carbohydrate). Most of the hybrids usually contain an even larger proportion of ears than the older open-pollinated varieties, and the silage will be fully as palatable and as high in feeding value.[5]

520. Late-maturing vs. earlier corn for silage.—In the North an important question is whether to grow for silage a variety of corn that is early enough to reach the early-dent stage or at least the late-dough stage in the average season, or to grow instead a taller-growing variety that will not usually reach these stages before frost. In most of the experiments on this question, it has been concluded that it is best to grow a variety which will generally reach the early-dent stage or at least the dough stage.[6] When the crop is planted at the proper rate, silage from such a variety will have a large proportion of ears and will therefore have a high nutritive value per ton.

The late varieties will produce a larger tonnage, but the forage will be much more watery. In actual amount of dry matter produced per acre there has usually been but little difference. Silage made from immature corn is apt to be much sourer than that from corn which has at least reached the dough stage, and it may not keep so well. Because of its higher water content and also because it contains little grain and is slightly less digestible, the value per ton will be considerably lower.

Silage from corn harvested at the milk stage or earlier supplies only 60 to 75 per cent as much total digestible nutrients per 100 lbs. as dent-stage silage. For each 100 lbs. of digestible nutrients in the silage, the expense of harvesting and ensiling the crop is therefore much greater in the case of the late varieties, and also much more silo space is required.

Usually the northern stockman who grows plenty of other roughage will wish to fill his silo with richer and more palatable feed than the late-maturing varieties supply. In case he has a very limited amount of corn land and desires to produce the largest possible tonnage of silage, he may decide to grow a late variety and plant it thickly. In feeding such silage, however, it must be remembered that it is low in dry matter. Therefore to prevent lower production of milk or meat, more hay or other dry roughage must be fed with it than in the case of silage from well-eared corn, cut at the dent stage.

It is important not to use for silage a variety that is so early that it will fail to utilize effectively the entire growing season. Such varieties produce much less feed per acre than a variety that just

reaches the desired silage stage in the average season.

If the crop has not reached the proper stage at the usual time for killing frosts to occur, it is best to let it stand until after frost rather than to ensile it when very immature, for satisfactory silage can be made from frosted corn, and the crop may mature to a considerable extent before a severe frost comes. If the crop is killed by frost, it should be ensiled quickly, before the leaves become dry. If the plants dry out before all the crop can be ensiled, enough water should be added as the silo is filled so that the cut forage will pack well.

When corn is ruined by drouth, the silo is the best means of saving all feeding value possible. Water should, of course, be added to the forage as it is ensiled, if it is too dry to pack well.

521. Value of corn silage.—Through the use of corn silage the cost of producing milk and meat can be materially lowered over much of this country. Not only is corn silage excellent for cattle and sheep, but it may be used in a limited way with horses that are idle or at light work. Corn silage is too bulky and fibrous to have much usefulness in feeding swine and poultry. As shown in Chapter XXXV, it gives satisfactory results for wintering bred sows when well supplemented with protein and minerals. However, legume hay is much more efficient for them, because of its high content of protein, vitamins, and calcium. The value and use of corn silage for dairy cattle, beef cattle, and sheep is discussed in later paragraphs.

Corn silage is used most commonly as only part of the roughage for stock, generally being fed in combination with hay or dry fodder. It gives especially good results when fed with legume hay or mixed hay rich in legumes. If corn silage is the only roughage, a calcium supplement, such as ground limestone, should be added to the ration, to ensure a plentiful supply of this mineral.

Silage from well-matured corn supplies slightly more than one-third as much total digestible nutrients per 100 lbs. as does good-quality hay. In experiments with dairy cows, good corn silage has actually been worth 33 to 40 per cent as much per ton as good legume or mixed hay. The feeding value of corn silage for dairy cows therefore agrees well with the amount of digestible nutrients it furnishes.

For fattening cattle and fattening sheep corn silage has an even higher value in comparison with hay. Numerous experiments have shown that for these classes of stock good corn silage is usually worth one-half as much per ton as good legume or mixed hay. This difference in the relative values of silage and hay for dairy cows and for fattening cattle or fattening sheep is somewhat surprising. It may perhaps be explained as follows:

Lambs chew their feed very thoroughly and therefore no corn kernels in the silage escape digestion. In the experiments with fattening cattle, pigs have commonly followed the cattle to salvage any kernels that passed through unchewed. Thus the combination of fattening cattle and pigs completely utilized the grain in the silage. On the other hand, in the case of dairy cows there is an appreciable loss of nutrients because some kernels escape chewing.

This difference in value does not mean that corn silage is an inefficient feed for dairy cows. As is pointed out later, wherever corn thrives, corn silage is usually the most economical succulent feed for winter feeding. The difference merely means that for fattening sheep and also for fattening cattle which are followed by pigs, well-eared corn silage has an even higher actual value than would be estimated from its chemical composition.

In considering the value of corn silage, it should be borne in mind that well-eared corn silage is a combination of roughage and concentrate. Such silage contains 1 pound of dry corn grain in each 7 to 9 lbs. of silage.[7] Therefore, when a dairy cow, for example, eats 30 lbs. a day of such silage, she gets 3 or 4 lbs. of corn grain in the silage. Experiments have shown that the corn grain in silage has the same feeding value as

the same amount of corn fed as the dry grain.[8]

Though corn silage is a very economical feed over much of this country, in some areas either hay as the only roughage or grass silage in combination with hay may be cheaper. (424)

522. Corn silage vs. corn fodder.—There is not a large difference in the amount of nutrients lost when a corn crop is cured as dry fodder under favorable conditions, and when it is ensiled. (426) However, in feeding experiments an acre of corn forage fed as silage has generally had a much greater value than an acre of the same crop fed in the form of dry fodder.

This is doubtless because stock usually reject the butts of the dry corn stalks, even when finely cut, while in silage they are mostly eaten. Moreover, owing to the great palatability of this succulent feed, silage-fed animals consume a larger ration, and more nutrients are hence available for milk or flesh production after meeting the needs for maintenance. Just as important as these advantages is the fact that, like other succulent feeds, silage has a beneficial laxative effect and aids in keeping stock thrifty.

523. Corn silage for dairy cattle.—Throughout the chief dairy districts of the United States, corn is by far the most popular and widely used silage crop for feeding dairy cattle. Not only does corn silage readily provide a uniform supply of high-quality succulent feed for winter, but also it is an excellent supplement to scanty pasture in summer.

A much greater feeding value is secured from an acre of corn when it is ensiled than when it is fed as dry fodder. For example, in an Iowa experiment dairy cows were fed either silage or corn fodder, along with alfalfa hay and a good concentrate mixture.[9] The dry corn fodder was worth only about 45 per cent as much per acre as corn silage. This was largely because of the greater loss in curing the fodder and the waste in feeding it, for the milk yield per cow was only 6 per cent less on the ration containing corn fodder than on the silage ration.

When silage is fed under proper conditions, the flavor or quality of the milk is not injured in the slightest degree. Silage should be fed after milking, the mangers should be cleaned out regularly, silage should not be left scattered on the floor of the stable, and the stable should be properly ventilated.

In a later chapter information is presented on the amounts of corn silage to be fed per head daily to cows under various conditions, and on the use of silage as the only roughage. (1076)

524. Value of corn silage when added to dairy rations.—Numerous experiments have been conducted to determine the effect on milk production when corn silage is added to a ration of hay and concentrates, and to find the relative feeding values per ton of silage and hay.[10] The effect produced by the addition of silage to the ration will depend chiefly on the quality of the hay that is fed and on whether or not there are drinking cups in the stable. When cows have access to water at all times, the addition of silage to a dry ration makes less difference than when they have water less frequently, because silage supplies considerable water.

If silage is added to a ration consisting of a good concentrate mixture and only fair dry roughage, such as ordinary grass hay or dry corn fodder, the milk yield will be considerably increased, even when water is always available. On the other hand, if the dry roughage is legume hay of excellent quality and the cows have access to drinking cups, sometimes there is no increase in milk production and when there is an increase it does not usually exceed 7 to 10 per cent.

In a study by the United States Department of Agriculture of records from cow-testing-association herds, it was found that the average production of cows on silage, legume hay, and grain was 305 lbs. of fat a year; on only legume hay and grain, 299 lbs.; on silage, mixed hay and grain, 279 lbs.; on only mixed hay and grain, 248 lbs.; and on only non-legume hay and grain, 229 lbs.[11] It will be noted that the addition

of silage to a ration of legume hay and grain increased the average production much less than adding it to a ration of poorer hay and grain.

Where the effect of silage feeding has been studied in surveys made in various states on the cost of milk production, it has usually been found that silage-fed herds produced more milk and fat than those fed only dry roughage in winter. However, in some studies the net return has been no larger or even smaller where silage has been fed.

Since a first-class dry ration produces nearly as much milk as when silage is added, one should base his decision as to whether or not to use silage chiefly on the relative cost of nutrients in silage and in hay. He should also consider the other farm management factors which have been discussed in a previous chapter. (**424**)

In the experiments in which silage has been added to a ration of hay and concentrates, it has usually required from 250 to 300 lbs. of well-eared corn silage to equal 100 lbs. of hay in actual feeding value. In these trials good corn silage has therefore been worth 33 to 40 per cent as much per ton as good hay. This is a somewhat lower value than corn silage has for fattening cattle or lambs, as has been mentioned previously.

525. Corn silage for beef cattle.—Silage from well-matured corn, carrying an abundance of ears and consequently a high proportion of corn grain, is the best of all silages for beef cattle. Such silage aids greatly in reducing the amount of grain or other concentrates needed for fattening cattle or for young cattle being carried through the winter. Since corn silage is low in protein, care should be taken to balance the ration with a sufficient amount of protein supplement, when it is one of the chief roughages.

The high value of corn silage for fattening cattle has been proved in numerous experiments. The results of 33 experiments show the effect of adding well-eared corn silage to the already excellent ration of shelled corn, protein supplement, and alfalfa or clover hay.[12] The steers, usually 2-year-olds, received 23.6 lbs. silage, 14.3 lbs. shelled corn, 3.1 lbs. hay, and 2.6 lbs. protein supplement per head daily and gained an average of 2.49 lbs. Those fed no silage gained nearly as rapidly and there was only a trifling difference in selling price in favor of the silage-fed cattle.

The chief advantage from feeding silage was the saving of corn and hay, and the cheapness of the gains. In these many trials each ton of corn silage saved an average of 247 lbs. corn plus 580 lbs. legume hay, but minus 14 lbs. protein supplement. With feeds at representative prices, corn silage was worth fully one-half as much per ton as good legume hay. In these trials, the feed cost of 100 lbs. gain was 5 per cent less for the cattle fed silage. This might make the difference between profit and a loss on the feeding operation.

In similar tests fattening calves fed corn silage in addition to shelled corn, protein supplement, and legume hay, gained a trifle more rapidly than others fed no silage and sold at a slightly higher price.[13] On the average, corn silage was worth 45 per cent as much as legume hay in these trials.

For carrying calves or older cattle through the winter for later fattening, corn silage has usually been worth fully one-half as much per ton as good legume hay.[14] Cattle wintered on corn silage, hay, and a small allowance of protein supplement will make considerably greater gains than those wintered without silage, unless grain is added to the latter ration. This is because of the grain that well-eared corn silage supplies.

Corn silage is also an excellent roughage for wintering beef breeding cows. In Maryland experiments a ration of corn silage supplemented with soybean oil meal and ground limestone was more satisfactory for beef cows than wintering them on mixed clover-timothy hay.[15] In 4 New York tests corn silage was worth 42 per cent as much per ton as good mixed hay when replacing half the hay in the ration for beef cows.[16]

We can conclude from the various experiments that where corn silage does

not cost more than about one-half as much per ton as alfalfa or other legume hay, the use of silage in addition to hay for beef cattle is thoroughly economical. Where silage costs more than this, in comparison with hay, it may be more profitable to feed hay as the only roughage.

It is shown in Chapter XXVIII that when corn silage is added to a ration of nothing but alfalfa hay for fattening cattle the gains are greatly increased. Each 100 lbs. of silage actually replace about 115 lbs. of hay, without giving credit for the better finish produced by the silage feeding.

Information is given in Chapter XXIX on the best amounts of corn or other silage to feed beef cattle, and on the use of silage as the only roughage.

526. Type of corn silage for beef cattle.—Corn for silage to be used for fattening cattle should be planted at a rate that will permit the development of good ears. This is because grain is needed for the rapid fattening of cattle. Also, in the northern states a variety of corn should be grown which will nearly mature in the average season, instead of raising a rank-growing, late-maturing kind.

Immature, watery corn silage is worth much less per ton than silage made from well-eared corn harvested at the dent stage. A decidedly lower feeding value per acre is therefore secured when the crop is ensiled too early. For example, in an Ohio trial well-matured silage produced 23 per cent more gain per acre on fattening cattle than did silage ensiled at the roasting-ear stage.[17]

527. Corn silage for sheep.—Corn silage is the most widely used succulent feed for the winter feeding of sheep in the United States. This is due both to its cheapness and to its high value for breeding sheep and fattening animals. Not only does it furnish palatable nutrients, but also it aids in preventing constipation. Only silage of good quality should be fed to sheep, for they are much more susceptible than are cattle to injurious effects from eating spoiled or moldy silage. Also, silage which is unduly sour is apt to cause colic and scours.

The value of corn silage for fattening lambs is well shown by the results of 44 experiments in which corn silage has been added to the excellent ration of shelled corn and alfalfa or clover hay.[18] In these experiments a total of 2,434 lambs averaging 60 lbs. in weight at the start were fed for an average of 91 days. In 19 of the trials a small amount of protein supplement was added to the silage ration, as a ration of corn grain, legume hay, and corn silage has slightly less protein than is needed for the most rapid gains.

The silage-fed lambs ate an average of 1.2 lbs. silage, 1.1 lbs. shelled corn, 1.2 lbs. alfalfa or clover hay, and 0.08 lb. supplement a day and gained 0.35 lb. daily. Those fed no silage ate 1.7 lbs. hay and 1.1 lbs. corn a day and gained a trifle less than those fed silage, 0.32 lb. The silage-fed lambs sold for 13 cents more per hundredweight, because of slightly better finish. The chief advantage of feeding silage was in the saving of grain and hay required per 100 lbs. gain. In these trials 1 ton of silage plus 118 lbs. protein supplement saved 1,038 lbs. legume hay and 197 lbs. shelled corn.

Considering not only the feed replaced by silage, but also the slightly more rapid gains and slightly higher selling price, we may conclude from these many trials that good corn silage, thus fed, is usually worth slightly more than one-half as much a ton as legume hay.

In most of the other experiments in which corn silage has been added to other rations the results have been similar.[19] In certain western tests corn silage has had a somewhat lower value when it has been added, usually in very limited amounts, to grain and excellent alfalfa hay.[20]

When fattening lambs are fed either corn or sorghum silage and also legume hay for roughage, it is best to let them have all the silage they will clean up, in addition to what legume hay they will take. This usually produces more rapid and cheaper gains than if the allowance of silage is limited.[21] In very cold weather care must be taken not to feed

more silage than will be eaten before it freezes.

It is interesting to note that lambs given all the silage they desire will still eat nearly as many pounds of hay as of silage, while steers fed the same feeds may eat 5 to 7 times as many pounds of silage as of hay.

When legume hay or good-quality mixed legume-and-grass hay can readily be provided, it is best not to use corn or sorghum silage as the only roughage for fattening lambs or for the breeding flock, but to feed some hay in addition. The legume hay not only helps supply protein, but also it furnishes calcium and supplies vitamin A and other vitamins. The use of corn or sorghum silage as the only roughage for sheep is discussed more fully in Chapter XXXI. If these silages are fed as the only roughages, it is very important to supply a sufficient amount of protein supplement, and also to add ground limestone or some other calcium supplement.

Several experiments have shown that corn silage has a decidedly higher value per ton for fattening lambs, when fed along with good hay, than it does as the only roughage. This is true even when a protein supplement and a calcium supplement are fed. For example, in 3 New York tests, corn silage was worth 56 per cent as much as alfalfa hay when added to a ration of shelled corn, protein supplement and alfalfa hay. However, when silage was fed as the only roughage with corn, protein supplement, and ground limestone, it was worth only 37 per cent as much as the hay.[22]

528. Corn silage for horses and mules.—While silage is fed to horses or mules much less frequently than to cattle or sheep, many farmers have had success in using it. Only silage of good quality, free from decay or mold, should ever be fed to horses, for they are much more apt to be poisoned by spoiled silage than are cattle or even sheep.

Silage should not be the only roughage for horses or mules, but it may replace one-third to one-half the hay usually fed. The animals should be accustomed to it gradually, and certain ones may not eat it readily at first. Because of its bulky nature, animals at hard work cannot consume much silage, but it is well suited to idle horses and mules, brood mares, and growing colts.[23] If the silage contains much corn, the amount of grain that is fed should be reduced accordingly.

529. Corn-fodder or corn-stover silage.—Silage can be made from dry corn or sorghum forage, if the forage is wet thoroughly as it is cut into the silo and if it is tramped down well, so there will not be too much air in the mass after it settles. Otherwise, the forage is apt to mold. When properly ensiled, such forage ferments much as does green fodder in the usual silage process. Though such silage is usually less palatable than silage from green fodder, it is eaten readily by stock and with less waste than in the case of dry fodder or stover.

The water can be sprinkled on the cut material in the silo, but it can be mixed more evenly if a stream is run into the blower, and then more water, if necessary, is sprinkled over the cut forage in the silo, as it is filled. Enough water should be added so that a little can be squeezed out of a handful of the cut material. Generally, about one ton of water should be added to each ton of dry forage.

Since corn-stover silage lacks the grain, it is worth decidedly less per ton than normal corn silage that includes the ears. However, it is more valuable than an equivalent amount of dry corn stover, for it is more palatable and it is eaten with less waste. It is best used for animals that do not need rations rich in digestible nutrients. For example, it is satisfactory as the chief roughage for wintering beef breeding cows (which are not nursing calves) or for wintering stocker cattle that are to be fattened on grass the next summer. If possible, good legume hay should be fed along with stover silage.

On the other hand, it is a mistake to remove the ears from corn forage for silage intended for dairy cows, dairy heifers, fattening beef cattle, beef calves, breeding ewes, or fattening sheep. These

animals all need rations rich in digestible nutrients. If the ears are removed, it will therefore be necessary to replace this grain by feeding larger amounts of concentrates. Even then, the results will usually not be so good as when normal silage, rich in ears, is fed.

530. Corn-stover silage for dairy cattle.—For feeding dairy cows, the labor of removing the ears from corn forage before ensiling it is more than wasted. Experiments many years ago proved clearly that better results are secured from normal well-eared silage than from stover silage, fed with the ground corn grain from the ears that had been removed.[24] Similar results were secured in a recent Michigan trial.[25] In a Wisconsin experiment corn-stover silage, fed with alfalfa hay and a good concentrate mixture, produced 10.6 per cent less milk than did normal corn silage.[26] The stover silage was worth only 61 per cent as much per ton as corn silage containing the ears.

531. Corn-stover silage for beef cattle.—The manner in which corn-stover silage can be used for wintering beef breeding cows is well shown by Illinois tests.[27] Beef cows wintered on 60 lbs. of corn-stover silage per head daily plus 1 lb. of protein supplement, and usually with a little straw in addition, were rather thin in condition but produced thrifty calves. The cost of feed was only one-third as much as with corn silage that contained all the ears. Thus fed, corn-stover silage will be worth from one-half to two-thirds as much per ton as corn silage containing the ears.

Use can also be made of stover silage as part of the roughage for wintering yearling or 2-year-old beef cattle, unless considerable gain in weight is desired during the winter.

Some farmers think that a considerable part of the value of the corn grain is lost when the whole crop is ensiled. They believe that if they husk the corn and later feed it with silage made from the stover, the crop will have a higher value. The contrary has been shown by Michigan and Tennessee experiments in which fattening cattle were fed either stover silage or well-eared corn silage as part of the ration.[28]

532. Dry corn fodder; shock corn.—Though not so palatable and valuable as corn silage, corn grown thickly and cured as dry fodder while the leaves are yet green, makes a coarse forage which may be used as a substitute for hay from the grasses.

As corn fodder is low in protein, it gives the best results when fed with legume hay. Such a combination is satisfactory for dairy cows, beef cattle, and sheep. Corn fodder may also be used as a substitute for hay with idle horses, brood mares, and colts.

Corn fodder and stover should be cured in large, well-made shocks, to reduce the losses from weathering. When corn forage seems dry, it generally still has more water and less dry matter than hay, a fact that should be borne in mind in feeding it. Corn fodder or stover must be well cured before it is stacked, and especially before it is stored in a mow. Otherwise, it will heat and mold badly.

When corn is grown primarily for grain, sometimes the crop is fed as *shock corn,* the stock doing their own husking and eating the corn grain and most of the stover. This method of feeding the crop saves enough labor to make it economical under some conditions, even though the feeding value per acre is commonly much less than when the corn is ensiled.

The relative value of shock corn or corn fodder per acre compared with corn silage will depend to a considerable extent on the usual amount of rainfall in autumn in the particular region. In the corn belt and other humid districts there is a considerably greater loss of nutrients in curing corn fodder in the field than there is in the drier regions.

When shock corn is husked by machinery, the stover is usually shredded or chopped at the same operation. Corn fodder is also often chopped with a silage cutter before feeding. This shredded or chopped material is no more digestible than the uncut forage. However, chopping or shredding usually reduces the wastage. Such forage is also easier to handle, and the waste is in better shape for bedding. Unless shredded or chopped fodder or stover is thoroughly dry, it will heat and mold if a large quantity is stored for any considerable period.

Grinding fodder or stover costs

much more than chopping or shredding it. Grinding is therefore probably not advisable, except that it may pay to grind well-eared fodder finely enough to crack the kernels for stock that would fail to chew the grain thoroughly.

533. Corn fodder for dairy cows.—Though inferior to silage, well-cured corn or sorghum fodder is relished by cows and may be used as a substitute for hay from the grasses. Instead of being fed as the only roughage, it should be used with some legume hay, and it should be chopped or shredded to reduce waste. The portion of corn or sorghum fodder that is eaten is about equal to timothy hay in value. Whole corn fodder was not a very satisfactory feed for dairy cows in Iowa and North Carolina tests.[29]

534. Shock corn; corn fodder for beef cattle.—Both shock corn and corn fodder are often used for beef cattle. Shock corn is frequently fed to fattening cattle, especially during the first part of the fattening period. The cattle soon become used to eating the unhusked ear corn and will also eat most of the leaves and even some of the stalks. In feeding shock corn there is more wastage of grain than in feeding ear corn or shelled corn, even when pigs follow the cattle. It is also rather difficult to adjust the amount of grain as the fattening progresses. The gains are therefore apt to be slower from shock corn, especially during the latter part of the feeding period.

Corn fodder and shock corn are excellent feeds for wintering beef cattle, when a limited amount of legume hay is supplied to balance the ration or when a small amount of protein supplement is fed. Though a considerably greater feeding value per acre is secured when the crop is ensiled, the dry fodder is a very useful feed for those who do not have silos.

In the corn belt and other humid regions, a much greater return per acre is generally secured when corn silage is fed to fattening cattle than when the crop is utilized as shock corn. Thus, in 3 Michigan experiments fattening cattle made fairly good gains on shock corn, fed with a protein supplement and a limited amount of alfalfa hay.[30] However, other cattle fed corn silage in place of the shock corn made somewhat greater gains. Still more important was the fact that the silage produced 55 per cent more gain in liveweight per acre than shock corn when fed uncut, and 15 per cent more than chopped or ground shock corn. Similar results have been secured in most other comparisons of corn silage and shock corn for fattening cattle.[31]

In the drier districts there may not be any great difference in the results from corn silage and from chopped or ground corn fodder as a feed for beef cattle, because the fodder can be cured with but little loss of nutrients. Thus, in Colorado, Nebraska, and North Dakota experiments chopped or ground corn fodder was nearly as satisfactory as corn silage.[32] In feeding value, 100 lbs. of chopped or ground fodder equalled 184 to 228 lbs. of corn silage.

Whether or not it will pay to chop or grind corn fodder or shock corn will depend, first of all, on whether pigs follow the cattle, and also on the quality of the forage and the cost of preparation. Where pigs followed the fattening cattle, it did not pay to chop or grind shock corn in Iowa and Michigan experiments.[33] If shock corn is fed to fattening cattle which are not followed by pigs, it will probably pay to grind the fodder fine enough to crack the corn kernels.

535. Corn fodder for sheep.—Well-cured dry corn fodder is a better roughage for sheep than most timothy hay or other grass hay. However, corn silage is decidedly preferable to the dry fodder and has a considerably higher value per acre. For feeding to sheep, corn fodder had best be chopped to reduce the wastage, instead of being fed uncut. Sometimes it is ground in a roughage mill.

Ground or finely chopped dry corn fodder, including the ears, was compared with corn silage in Colorado and New Mexico trials with fattening lambs, which were fed alfalfa hay and concentrates in addition.[34] The gains were about as rapid on the corn fodder as on corn silage, and

1.0 ton of the chopped or ground dry fodder was equal to 2.5 tons of corn silage in feeding value.

The use of shock corn, grown primarily for the grain, in fattening lambs is discussed in a later chapter. (699)

536. Corn fodder for horses and mules.—Properly-cured corn fodder (especially that thickly grown for forage) is a satisfactory substitute for timothy or other grass hay in feeding idle work stock or animals at moderate work, and for brood mares, stallions, and growing stock. An economical combination for wintering farm horses or mules is half corn fodder or stover and half legume hay. For idle horses, no grain will be needed in addition, except for a few weeks before the spring work begins.

The portion of good corn fodder that is actually eaten is about equal to timothy hay in feeding value. To reduce the waste, it is best to cut or shred the fodder. Even then, there will usually be considerable refuse, but this can be used for bedding.

537. Corn stover.—Though corn stover, the forage which remains after removing the ears from shock corn, is not a high-grade roughage, it has considerable value when properly used. Stover produced in the northern part of the corn belt is superior to that grown in the South. As soon as corn stover is well cured, it should be stacked or placed under cover, rather than being left to waste away in the shock. When corn develops but little grain, because of drouth or hot winds at silking time, the stalks and leaves are higher in digestible nutrients than usual.

IN STOCK FARMING CORN STOVER IS UTILIZED

Corn stover contains at least one-fourth the feeding value of the corn crop. In well-planned stock farming it is well utilized.

In the corn belt the ears are commonly husked or snapped from the standing stalks, and the stover then left uncut in the field. On livestock farms horses, cattle, or sheep are usually turned into these stalk fields to utilize the stover and to get any remaining ears. Considerable feeding value can thus be saved, though the wastage is greater than when the crop is harvested and husked.

Corn stover is too low in nutrients to form any large part of the roughage for high-producing dairy cows. A limited amount of bright, well-cured stover, fed after cutting or shredding, may sometimes be an economical feed for the milking herd. However, better use can us-

ually be made of the stover by feeding it to well-grown heifers, idle horses, or other stock which need less nutrients.

Corn stover can often be fed advantageously as part of the ration for wintering beef cows or even for wintering young beef cattle, but it is too low in nutrients to be of much value for fattening cattle. For example, in an Ohio trial, fattening steers fed corn stover with mixed hay, shelled corn, and protein supplement returned only 81 cents per head

538. Corn as a soiling crop.—Corn ranks high as a soiling crop, because of its palatability, the high yield of nutrients, and the fact that it remains in good condition for feeding during a much longer time than many of the other soiling crops. Green corn fodder is of especial value for dairy cows when pastures are short in late summer or early fall. An acre of ripening corn thus fed in early fall may return twice as much profit as if it were held over until winter.

In Grain Farming Corn Stover Is Largely Wasted

In exclusive grain farming in the corn belt, the ears are picked from the standing stalks, and the stover is then often allowed to waste away in the field.

over cost of feed, while others fed corn silage in place of the stover gave a net return of $6.14.[35]

Corn stover is likewise unsuitable for fattening lambs,[36] but cut or shredded stover may be used as part of the roughage for breeding ewes, if considerable good legume hay is fed in addition.

Corn stover, if well-cured, is satisfactory as part of the roughage for wintering idle horses or mules, especially when fed with legume hay or mixed hay. It does not supply enough net energy to be very useful for horses or mules at work.

For early feeding, sweet corn may often be advantageously used.

If cattle are turned in a field to graze on green corn (forage and ears) before it has matured, they may overeat, causing serious digestive disturbance.

539. Pulling fodder.—In the South the tops of the ripening corn stalks are often cut off just above the ears, leaving the tall butts, each with an unhusked ear at its top. Next the leaves are stripped from the butts, and these together with the severed tops are cured into a nutritious, palatable fodder, which is used for stock feeding. However, "pulling fodder" in this manner is a very unwise practice, for it seriously reduces the yield of grain. During the last stages of its

life the corn plant is busiest in manufacturing and storing nutrients. Removing the top and leaves at once stops all this work of food making.

540. Sweet-corn stover; corn-canning-factory waste.—*Sweet-corn stover,* left after the green ears have been removed for sale on the market or to a canning factory, is of somewhat higher value per ton, on the dry basis, than stover from ripe field corn. It is more leafy, and the leaves and stalks are more nutritious. Silage made from green sweet-corn stover is worth nearly as much per ton as that made from immature field corn which contains but little grain.

The sweet-corn forage should be allowed to mature a few days after the ears are removed, before it is ensiled. It then will be less watery, and the silage will not be too acid. However, it should be ensiled when the stalks and most of the leaves are still green.

The *canning-factory waste* at corn canneries consists of the husks and cobs, with some ears of unsatisfactory quality for canning. This waste is usually ensiled, either in stacks at the factory or in silos on the farms of the growers. Such silage is lower in protein and in total digestible nutrients than silage made from well-matured field corn that has a good proportion of ears. Judging from its composition and digestibility, it is worth about as much per ton as silage from field corn that has but little grain.[37] Silage made from canning-factory waste is sometimes very acid, and may then be rather unpalatable to stock.

541. Corn tassels.—Corn tassels, usually discarded after being clipped from corn plants in producing hybrid corn seed, have been found to be rich in carotene and B-complex vitamins and fairly high in protein.[38] It is estimated that the yield of tassels on the dry basis is about 270 lbs. per acre. If this material could be saved economically, it might well be used for stock feeding.

II. The Sorghums

542. Importance of the sorghums.—In the central and southern parts of the western plains states, the sorghums (*Sorghum vulgare*) are of great importance as feed crops, both for forage and for grain. In fact, success in stock farming throughout this section depends largely on the sorghums. Because they are much more drouth-resistant than corn, they have largely taken its place in those portions of this region that have too little rainfall for corn.

The importance of the sorghums in the United States is shown by the fact that as much as 17,000,000 acres are grown annually. Of the total acreage, more than half is usually raised for grain, only about a million acres for silage and the rest for dry fodder. Of our acreage, all but a small percentage is grown in ten states—Texas, Kansas, Oklahoma, Colorado, Nebraska, New Mexico, Missouri, South Dakota, Arizona, and California.

Sorghums are also important as forage crops in certain sections of the South where they yield much more forage per acre than corn, since they produce a fair crop on soil too poor or thin for corn.

Where there is sufficient rainfall, corn usually excels the sorghums, both for grain production and for forage. For this reason the acreage of the sorghums is small in the corn belt and eastward. However, corn requires a plentiful supply of moisture throughout the growing season, and the yield is always unsatisfactory if growth is seriously checked by drouth.

The sorghums will cease growing and the edges of the leaves roll together during periods of drouth and extreme heat. Yet, when rain comes, the plants quickly resume growth, unless they have been killed by the drouth. In the drier parts of the sorghum belt, milo and other dwarf varieties are grown which not only are more drouth resistant but also evade drouth, because they are early maturing. Like corn, the sorghums require warm weather throughout the growing season. In fact, they are even more particular than corn in this respect.

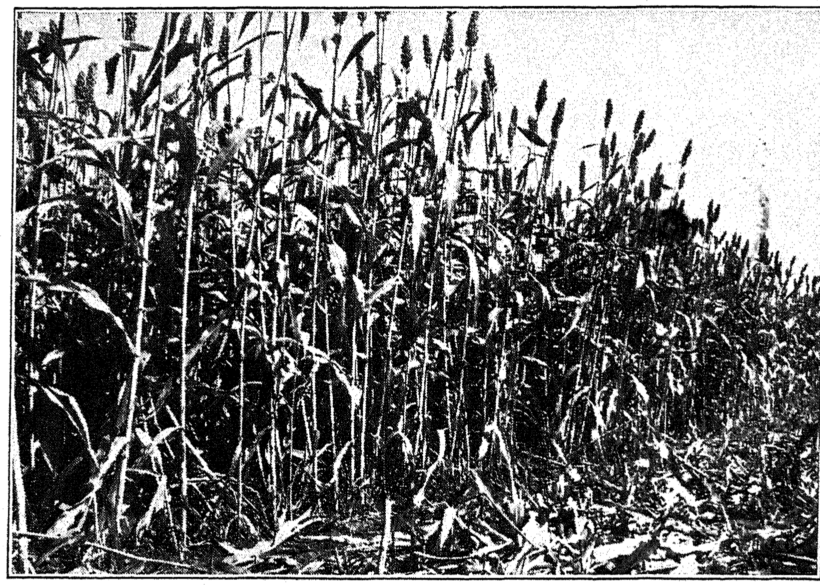
543. Types of sorghums.—The sorghums are of two general types—the *sweet sorghums,* or *sorghos,* which have stems filled with sweet juice, and the *grain sorghums,* which have juice that is not sweet or only slightly sweet and which usually have more pithy stems. *Broom corn* is another type of sorghum that is raised for the heads, or brushes, which are used in the manufacture of brooms. When the term "sorghum" is

used without the words "sweet" or "grain," in referring to silage, fodder, or stover, the product from sweet sorghum is usually meant.

The sweet sorghums, or sorgos, often called "cane" by farmers, are forage rather than grain producers. They are usually 5 to 7 feet tall or more. In most sections of the sorghum belt the varieties of sweet sorghum that are adapted to the particular locality give larger yields of forage per acre than the best grain sorghums.

rather dry, pithy stalks. They are not commonly grown for forage.

The taller grain sorghums, such as kafir and hegari, are used for both grain and forage. Atlas, Axtell, Ellis, and Norkan, which are crosses between grain sorghum and sweet sorghum, are also used for both forage and grain. Darso, shrock, and sagrain are other sorghums produced by such crosses, which are grown in some areas. These dual-purpose sorghums are leafy and have juicy, sweet stalks.



ATLAS SORGHUM GROWN FOR SILAGE

Atlas sorghum is one of the most popular varieties of sorghum for forage in the eastern part of the sorghum belt.

The two types of sorghum cross freely. Through crossing, certain hybrid varieties have been developed that combine some of the characteristics of both the grain sorghums and the sweet sorghums.

The sorghums now grown for grain in the sorghum belt are now mostly dwarf varieties, which can readily be combined. These varieties, mostly developed by crossing milo with kafir or other sorghums, grow only 2 to 4 feet tall, have erect heads, and usually have

544. Composition and nutritive value of sorghum forage.—Sorghum forage resembles corn forage in composition, but unless it has a high proportion of grain, it will have decidedly less total digestible nutrients than well-eared corn forage.

Another reason for a somewhat lower content of total digestible nutrients in sorghum forage for cattle is that they do not utilize the grain in sorghum fodder or silage quite so well as they do the grain in corn fodder or silage. Because

the grain is much smaller in size, somewhat more escapes chewing and passes through the digestive tract with little change. There is not this difference in the case of sheep, since they chew their feed more thoroughly.

Since sorghum grain is lacking in carotene, sorghum forage which includes the grain will have considerably less vitamin A value than well-eared corn forage of yellow corn varieties. Indeed, in Texas experiments with beef calves fattened in dry lot over long periods, sorghum silage, fed as the only roughage, did not supply enough vitamin A value to meet their needs fully.[39] They often began to show slight symptoms of vitamin A deficiency before they were ready for market. The lack of vitamin A can be readily corrected by feeding a pound or so of good-quality alfafa hay per head daily.

When sorghum forage, either silage or dry fodder, is fed as the only roughage for no longer than the usual feeding period, the difference in vitamin A value is the only great difference in nutritive value between sorghum forage and corn forage. However, in long-time Kansas experiments in which sorghum forage and sorghum grain were fed continuously to dairy cattle, without any pasture, other deficiencies showed up, even when protein and mineral supplements were provided.[40] Cows so fed eventually became unthrifty and produced much less milk than when legume hay was fed in addition. Similar results were secured in New Mexico and Nebraska experiments.[41]

It has been stated in Chapter VIII that there seems to be more trouble from urinary calculi in cattle and sheep when sweet sorghum forage is fed than with other roughages, possibly due to a high content of silicates. (250)

545. Prussic acid in sorghum forage.—Green sorghum plants of most varieties may contain sufficient prussic acid, or hydrocyanic acid, to cause the death of cattle or sheep, as is pointed out later. (**670**) The prussic acid content is apt to be high enough to be dangerous in young plants and when the growth is checked by drouth or other injury.

If sorghum is harvested when approaching maturity, it is not usually dangerous. Also, the prussic acid is destroyed to a considerable extent when the forage is thoroughly dried as dry fodder or hay, and it is still more completely destroyed when the crop is ensiled. Therefore well-dried sorghum is generally safe, and practically no cases of prussic acid poisoning have been reported from sorghum silage. Even green sorghum rarely causes prussic acid poisoning in the humid sections of the southern states. Low-prussic-acid varieties of sorghums have recently been developed which have not been known to cause poisoning of stock, even when pastured.[42]

Sorghum grain never causes prussic acid poisoning.

546. Sorghum fodder or hay.—Dry sorghum fodder, often called "bundle feed," is of great importance for stock feeding in the sorghum-growing districts. Indeed, the acreage of sorghums grown for dry fodder in this country is nearly as large as the acreage raised for grain, and it is several times as large as the acreage grown for silage.

For dry forage, varieties of sorghum with sweet, juicy stalks are generally grown, as the forage is more palatable. The crop should be cut when the seed is in the dough stage. Sorghum fodder or hay must be thoroughly cured in shocks, windrows, or cocks before it is stacked or stored in the barn, or it will sour or mold. In humid regions it had best be left in the field in shocks or cocks, and drawn to the feed lot or barn from week to week during the barn-feeding season, as it is difficult to get the stalks dry enough for storage in bulk.

Sweet-sorghum hay or fodder, often called "cane hay," is lower in fiber and slightly higher in total digestible nutrients than average timothy or prairie hay, but there is more waste in feeding it unless it is cut or shredded. Because of its sweetness, it is somewhat more palatable than corn fodder. Fodder from the grain sorghums, including the grain, may have as high a value per ton as that

from sweet sorghum. Though the stalks are less nutritious, the proportion of grain is usually larger.

Sorghum fodder harvested when the leaves were no longer very green was deficient in carotene in New Mexico trials, while early-cut, well-cured fodder had plenty for dairy cows.[43]

Well-cured sorghum fodder or hay is a satisfactory roughage for dairy cattle, beef cattle, sheep, and horses, when fed in a well-balanced ration. The value per ton will vary widely, depending on the leafiness, on the proportion of grain, and on how well it is cured. Except for work horses, it usually gives the best results when fed with some legume hay. If no legume hay is available, ground limestone or some other calcium supplement should be supplied. Except in very dry regions where the sorghum can be cured into excellent dry fodder with only a small loss of nutrients, a much higher feeding value per acre is secured from sorghum silage than from sorghum fodder.

Whether or not it will pay to chop or grind sorghum fodder will depend on the proportion that would be wasted if it is fed whole. For example, in a Texas trial chopping rather poor-quality grain sorghum fodder increased the value for fattening cattle enough to justify the expense.[44] On the other hand, in Kansas tests chopping good-quality kafir fodder did not increase its value for beef cattle being carried through the winter.[45] Grinding the fodder in a mill that cracked most of the grain did, however, increase its value considerably.

547. Sorghum fodder for dairy cattle.—In the plains states and in the South, sorghum fodder is a common feed for dairy cattle, resembling corn fodder in feeding value. It had best be fed with some legume forage, and even then it is usually of lower value than sorghum or corn silage, on the dry matter basis. Chopping or shredding sorghum fodder for dairy cattle is advisable to lessen the wastage.

548. Sorghum fodder or hay for beef cattle.—Cured forage from the sweet sorghums and the grain sorghums can be used for beef cattle in the same manner as corn fodder.[46] Sorghum hay, or "cane hay," made from thickly-planted sweet sorghum, is about equal to good prairie or timothy hay, for there is but little waste in feeding it.

Sorghum forage gives especially good results when fed with a limited amount of legume hay. However, chopped or ground sorghum fodder of good quality has been satisfactory as the only roughage for fattening cattle when fed with a sufficient amount of protein supplement to balance the ration and also with about 0.1 lb. per head daily of ground limestone or other calcium supplement.

Although sorghum fodder is a very satisfactory feed for beef cattle, a much greater feeding value per acre is secured when the crop is ensiled, except in districts where the autumns are very dry.

549. Sorghum fodder or hay for sheep.—For fattening lambs, sorghum fodder or hay usually gives decidedly better results when some legume hay is fed in addition than when it is the only roughage.[47] In some tests the results have been satisfactory, however, with chopped or ground sorghum fodder as the only roughage, when plenty of protein supplement and also a calcium supplement were supplied.[48]

Sorghum fodder is a good feed for wintering ewes if it is properly supplemented. Including some legume hay or other legume forage in the ration is desirable as insurance against nutritive deficiencies. However, in South Dakota trials sorghum fodder, with a protein supplement and minerals, was satisfactory as the only roughage for ewes.[49]

550. Sorghum fodder or hay for horses and mules.—Well-cured sorghum fodder or hay is excellent for horses and mules, and is satisfactory as the only roughage for mature horses. In a Nebraska test sorghum fodder was superior to prairie hay as part of the ration for colts.[50] Moldy, decayed sorghum forage is dangerous to horses.

551. Sorghum stover.—Sorghum stover (sorghum fodder from which the

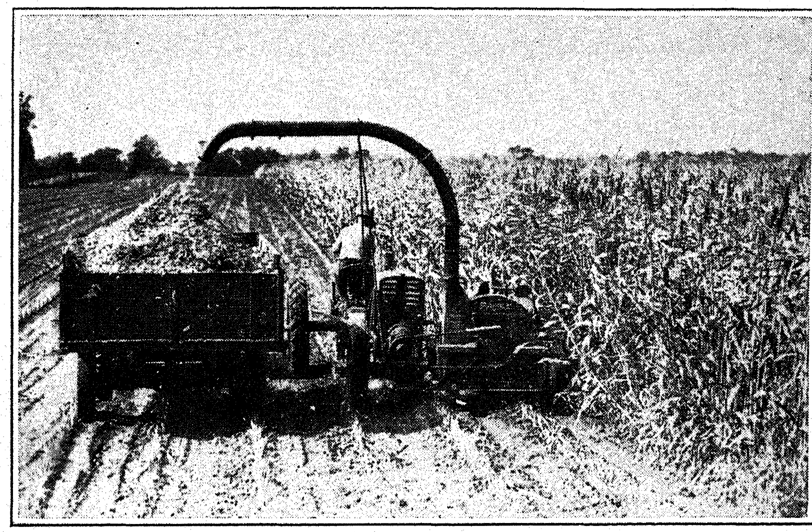
heads have been removed) is similar to corn stover in composition and general value. Stover from kafir, hegari, darso, or the sweet sorghums is the best, as it is leafier and the stalks are more nutritious than in the case of stover from milo, kaoliang, or durra.

Like corn stover, sorghum stover is best used for stock which is not being fed for high production. Thus, it is more valuable for wintering beef breeding cows, stocker cattle, or work stock than it is for milk cows, for fattening cattle or lambs, or for horses or mules at hard work. Since sorghum stover is very low in protein and may be deficient in calcium, supplements should be fed to meet these lacks when the stover is not fed with legume roughage.

For wintering beef calves sorghum stover was about equal to prairie hay in a Nebraska test, but inferior to sorghum silage.[51] Ground hegari stover, undoubtedly of good quality, was satisfactory as the only roughage for fattening calves in Texas trials.[52]

In Kansas trials ground sorghum stover was a satisfactory and economical roughage for fattening lambs, especially when fed with some alfalfa hay.[53] In a New Mexico test chopped sorghum stover was a better roughage than cottonseed hulls or corn stover for fattening lambs.[54]

552. Sorghum silage; sorghum-stover silage.—The sorghums make excellent silage if ensiled when the seeds are hard and ripe. Such silage contains no more acid than does corn silage and is well liked by stock. If the plants are immature, the silage will be too sour. Also, the crop will have much less feeding value per acre if ensiled before the storage of nutrients in the seeds is practically completed. For example, in Arkansas experiments with beef calves, Atlas sorghum ensiled when well matured or at least in the early dough stage produced more than twice as much gain per acre as did silage made at the early boot stage.[55]



HARVESTING SORGHUM FOR SILAGE WITH A FIELD CHOPPER

A sorghum crop has a much higher feeding value when it is ensiled, than when it is fed as dry fodder or hay.

A good way to determine whether sweet sorghum or kafir is mature enough for silage is to twist the stalk with the hands. If just a little juice is visible on the twisted cane, the proper stage has

been reached. If the crop does not mature enough before frost, fairly good silage can be made by allowing it to dry out somewhat before ensiling it. Also, immature sorghum which has been withered by drouth can be used successfully for silage. Water should be added, if the forage is too dry to pack well in the silo.

A sorghum crop has a much higher feeding value per acre when ensiled than when fed as dry fodder or hay. In spite of this fact, about 5 times as many acres are grown for dry fodder as for silage. Some farmers who use sorghum fodder have too few cattle to keep silage from spoiling. Others find the dry fodder more convenient to use as a supplement to winter range or pasture.

Sorghum silage is excellent for dairy cattle, beef cattle, and sheep. If sorghum silage is fed to horses, the same precautions should be taken as with corn silage. (**528**) The value per ton of sorghum silage is usually somewhat less than that of well-eared corn silage, because sorghum silage is not so rich in grain. Also, cattle do not chew the seed in sorghum silage as thoroughly as they do corn grain. A considerable percentage, therefore, passes through undigested. However, in the sorghum belt the yield of the sorghums is so much greater than that of corn that they far surpass corn for silage. This is also the case in certain sections of the South. There is generally no danger from prussic acid poisoning in feeding sorghum silage to stock.

Trench or pit silos provide a cheap means of storing silage in the sorghum belt and are therefore widely used. Since sorghum silage keeps well from one year to another, or even longer, many farmers in the dry-farming districts store silage in a good year to carry over to a time of drouth.

Silage is sometimes made from sorghum stover, after the heads are harvested. Since the silage can be made from the leaves and stalks while still green, sorghum-stover silage is more palatable to stock than silage made from dry corn stover with the addition of water. Also, for cattle there is not quite so much difference between the value of sorghum silage containing the heads and of sorghum-stover silage, as there is between normal corn silage and corn-stover silage. This is because more of the seed escapes chewing in the case of sorghum silage. Sorghum-stover silage was worth 87 per cent as much per ton as sorghum silage containing the heads in Oklahoma tests with dairy cows, and about 74 per cent as much in Kansas tests with beef calves being wintered.[56]

Because of its lower content of nutrients, stover silage had generally best be used for wintering beef cows, stocker cattle, or well-grown dairy heifers, instead of for cows in milk or for fattening cattle.

553. Sorghum silage for dairy cattle.—Sorghum silage ranks next to corn silage in value for dairy cattle. It is worth somewhat less per ton than such corn silage as is normally produced in the corn belt. However, where the climatic conditions are more favorable to the sorghums than to corn, as in the southern plains states, sorghum silage may be nearly as valuable per ton as the corn silage produced there.[57]

Sorghum silage has this high value for dairy cows in spite of the fact that a much larger proportion of the seed passes through the animal unmasticated and undigested than in the case of corn silage. It has been found that one-fourth or more of the seeds in sorghum silage are voided in the manure with little change.[58] This is a much larger loss than occurs in the case of corn silage.

There is apparently not much difference in the value per ton of silage from the grain sorghums and from the sweet sorghums for dairy cows, judging from the results of Kansas and Oklahoma tests.[59]

554. Sorghum silage for beef cattle.—Sorghum silage is of great importance for beef production in those sections where the climate is such that the sorghums yield much more forage per acre than corn. Except where weather conditions in the fall are ideal for curing sorghum as dry fodder, the feeding value

of sorghum silage per acre will be considerably greater than that of sorghum fodder.

Sweet sorghum silage is generally worth somewhat less per ton for beef cattle than silage from the grain sorghums or such hybrids as Atlas sorghum, as it contains much less grain. However, in many districts the yield of the sweet sorghums is enough greater to more than make up this difference.

When sorghum silage is added to a ration for beef cattle in which the only roughage is alfalfa or other hay, sorghum silage will usually be worth 30 to 40 per cent as much per ton as alfalfa hay, or about one-half as much per ton as prairie hay or oat hay.[60] If fed as the only roughage, its value will tend to be slightly lower than this.

For beef cattle that are being wintered on moderate rations, the value of sorghum silage per ton approaches that of such corn silage as is generally produced in the plains states. In 7 Kansas and Nebraska tests in which calves were wintered on either sorghum silage or corn silage with 1 lb. per head daily of cottonseed meal, the gain has been nearly as great on the sorghum silage.[61] Each 100 lbs. of sorghum silage were equal in average feeding value to 87 lbs. of corn silage.

For fattening cattle the value of Atlas sorghum silage or sweet-sorghum silage has been considerably lower than that of such well-eared corn silage as is commonly produced in the corn belt. For example, in Indiana and Illinois trials fattening cattle made nearly as rapid gains on Atlas silage as the main roughage as others did on corn silage.[62] However, in the Illinois trials the Atlas silage was worth only 60 per cent as much as corn silage for fattening cattle and 70 per cent as much for wintering beef calves.

In 15 other tests cattle gained 1.78 lbs. per head daily, on the average, on sweet-sorghum silage and 1.99 lbs. on corn silage.[63] On account of poorer finish, the cattle fed sorghum silage generally sold for a slightly lower price. Due to this and because somewhat more feed was required per 100 lbs. gain on sorghum silage, the actual feeding value of sorghum silage was only 58 per cent as great per ton as that of corn silage. These results show that sweet sorghum should not be grown in place of corn silage for fattening cattle, unless the average yield is enough larger to make up the difference in value per ton.

555. Sorghum silage for sheep.—Sorghum silage is a good substitute for corn silage in feeding sheep.[64] Except in the drier regions where sorghum fodder can be cured with little loss of nutrients, a higher value per acre is secured when the crop is ensiled than when it is fed as dry fodder.

Like corn silage, sorghum silage usually gives decidedly better results for fattening lambs or breeding ewes when fed in combination with some legume or mixed hay than when used as the only roughage. This is true even when protein and calcium supplements are properly provided.

In Kansas and Texas tests it required only 2.3 tons of sweet-sorghum silage to equal 1 ton of ground sweet-sorghum fodder for fattening lambs.[65]

556. The sorghums for pasture and as soiling crops.—The common varieties of sorghum are not generally used for cattle or sheep pasture, because of the danger of prussic acid poisoning. **(670)** Sudan grass is generally used instead, for it is not only much safer, but it is also a better pasture crop. Horses and swine can be grazed safely on sorghum. However, sorghum has too much fiber to rank high as a pasture for pigs. For older hogs fed considerable grain, it gives somewhat better results.[66]

Except for the danger of prussic acid poisoning, the sorghums are satisfactory as soiling crops. If the crop is allowed to reach the seed stage before it is fed, the danger is slight.

557. Dehydrated sorghum forage.—Sometimes sorghum fodder is dehydrated, in the same manner as alfalfa. This efficiently preserves the nutrients, but is expensive. In a Kansas test with dairy cows dehydrated Atlas sorghum had the same value as Atlas silage per pound of dry matter.[67] In another

Kansas trial with fattening lambs a pelleted ration made up of dehydrated sorghum, sorghum grain, and cottonseed meal produced slightly more rapid but decidedly more expensive gains than a ration of ground sorghum fodder, whole sorghum grain, and cottonseed meal.[68]

558. Perennial hybrid sorghums.—In Argentina a natural hybrid between sweet sorghum and Johnson grass (*Sorghum almum*) is a good perennial pasture crop in the drier areas. This does not spread by rootstalks and become a pest, as does Johnson grass. It has given promising results in Georgia.[69] Perennial sorghum hybrids are also being studied at the Mississippi and Hawaii Stations.[70]

559. Broom-corn-stover silage.—Many farmers believe that the broom-corn stover which is left after the brush is harvested is valueless or actually injurious for feeding. However, in Illinois tests broom-corn stover made fairly satisfactory silage when ensiled as soon as the brush was harvested and when 100 lbs. of molasses were added per ton.[71] Silage made without molasses did not keep well. The silage was somewhat less palatable to dairy cows than normal silage, but they ate it readily after becoming used to it and produced only slightly less milk than when fed corn silage.

QUESTIONS

1. What are the merits of corn as a forage crop?
2. Define corn fodder; shock corn; corn stover.
3. What factors should determine how closely corn should be planted for forage?
4. Explain why corn should not generally be cut for silage until the glazing stage.
5. State the main facts concerning the composition of corn forage, considering content of protein, total digestible nutrients, calcium, phosphorus, vitamin A value, and vitamin D.
6. Approximately what part of the digestible protein and net energy of a corn crop grown for grain is in the stover?
7. Why does corn excel as a silage crop?
8. Under what conditions might you advise a dairyman in the northern states to grow a late-maturing variety of corn for silage?
9. Why does an acre of corn silage generally have a decidedly higher value than an acre of dry corn fodder?
10. Discuss the value of corn silage for dairy cattle, stating the approximate value per ton of corn silage and good hay.
11. Similarly, discuss the value of corn silage for: (a) Beef cattle; (b) sheep; (c) horses and mules.
12. What type of corn silage is best for fattening cattle?
13. Discuss the making and use of corn-fodder silage and corn-stover silage.
14. Discuss the use of corn fodder for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules.
15. For what classes of stock and in what manner can corn stover be used best?
16. How does corn rank as a soiling crop?
17. In what sections of the country are the sorghums superior to corn for forage?
18. What are the differences between the sweet sorghums and the grain sorghums?
19. If sorghums are important in your region, describe the characteristics of the 3 chief varieties raised there.
20. Discuss the composition and nutritive value of sorghum forage.
21. Discuss the use of sorghum fodder for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules.
22. For what classes of stock is sorghum stover most suitable?
23. Discuss the value of sorghum silage for: (a) Dairy cattle; (b) beef cattle; (c) sheep.
24. Why is not sorghum used widely as a pasture for cattle or sheep?

CHAPTER XVIII

THE HAY AND PASTURE GRASSES—THE CEREALS FOR FORAGE—STRAW

I. The Grasses; the Cereals for Forage

560. The hay and pasture grasses.—The hay and pasture grasses are mostly perennials which thrive without yearly tillage, producing roughage of good. quality with little expense for labor. The grasses are also of great importance for building up the soil by adding humus. Moreover, they bind the soil together and prevent erosion because of the tremendous root systems. It has been estimated that in the top three inches of soil in a field of Kentucky bluegrass there are over 160,000 miles of roots per acre.[1]

The grasses are divided into two classes—the sod-formers and the non-sod-formers. The sod-formers, which spread by creeping rootstocks either above or below ground and make a smooth turf, include our most valuable pasture and lawn grasses, such as Kentucky bluegrass and Bermuda grass. The non-sod-formers, such as orchard grass, grow in tufts or bunches and increase only by seed or by stooling, except in the case of a few, such as timothy, which also increase to a limited extent by forming new bulb-like enlargements at the base of the stems.

The effect of various factors on the composition of pasture and hay crops has been discussed in Chapters XIII and XIV. Also, information is there given about the use and management of pastures and concerning haymaking.

561. Combinations for meadows and pastures.—A mixture of one or more grasses, combined with suitable legumes, is generally preferable to any single variety of grass for permanent pastures or meadows. Not only will the mixture provide a larger yield, but also the stand will be more permanent. A simple mixture, such as alfalfa or Ladino clover with a single grass, such as bromegrass, timothy, or orchard grass may be equal to or even excel a more complex mixture. Advice concerning the best mixture for local conditions can readily be secured from the county agricultural agent or the state college of agriculture.

For permanent pastures the chief reliance should be placed on those plants that are high-yielding and also permanent. However, some grasses of this type, such as Kentucky bluegrass, require time to become well established. It is, therefore, advisable to include with such a grass quick-growing plants to furnish forage while the slower-developing kind is becoming established. For this reason, such species as timothy and alsike clover are very often added to pasture mixtures, although these plants will usually be crowded out in a few years by the longer-lived kinds.

562. Composition and nutritive value of the grasses.—Before we consider the characteristics and usefulness of the various grasses, it is important to understand their general composition and nutritive value. While differing to some extent in palatability and feeding value, most of the grasses resemble each other in composition and value.

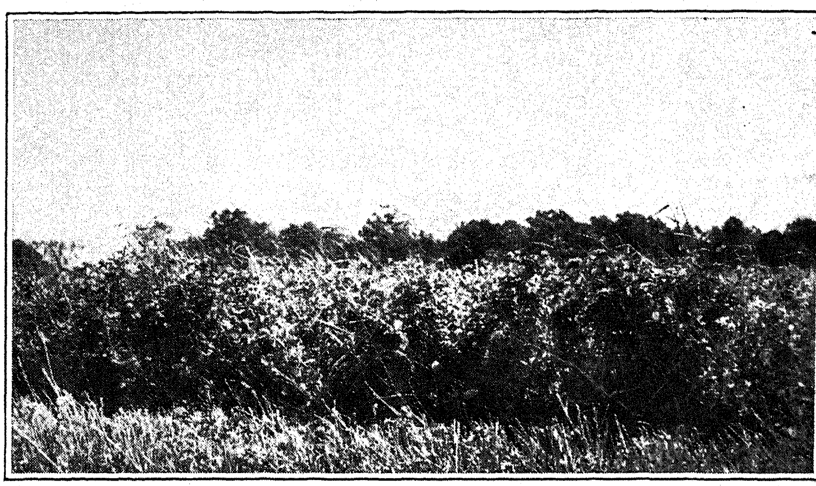
The great differences in composition and nutritive value of grasses at young stages of growth and when they are more mature have been emphasized in Chapters XIII and XIV. On the dry basis, young grass is far higher in protein, minerals, and vitamins than more mature grass, and it is much lower in fiber and especially in lignin (which has little feeding value). Young grass therefore is much higher in total digestible nutrients or net energy than at later stages.

When grass becomes mature and weathered, it resembles straw in composition and feeding value. It is poor in protein, it is low in digestibility, it may be very deficient in phosphorus, and it has practically no carotene.

The great changes in composition as grass advances in growth greatly affect the palatability and nutritive value of grass hay and of pasture forage. Early-cut grass hay from well fertilized fields may equal or approach legume hay in value for dairy cows and beef cattle, except that it is lower in protein and therefore a greater amount of protein supplement is needed with it. Such early-cut grass hay is even satisfactory for sheep, if fed with some legume hay or silage. On the other hand, late-cut grass hay is a poor roughage for milk cows and still poorer for sheep. When such hay must be used up, it is most suitable as part of the roughage for wintering beef breeding cows, stocker cattle, or well-grown dairy heifers, or for feeding horses or mules.

Even early-cut grass hay cured in the ordinary manner is not a satisfactory substitute for alfalfa or other legume hay in feeding swine or poultry. However, dehydrated very young forage from grass or small grains can be used for this purpose. (**416, 586**)

When grass hay is fed as the only roughage or with other non-legume roughage to dairy cattle, beef cattle, sheep, brood mares, or growing colts, ground limestone or some other calcium supplement should be supplied, unless one knows that the hay has plenty of calcium. The amount of protein supplement that is required to balance such a ration will ordinarily furnish sufficient phosphorus.



A HEAVY CROP OF MIXED LEGUMES AND GRASS

Such mixtures provide excellent hay or silage, much richer in protein than that from grass alone. (From New York State College of Agriculture.)

Mixed grass-and-legume hay is decidedly superior to grass hay, wherever legume hay crops thrive. Not only will a suitable combination usually produce much more hay per acre than grasses alone, but also the hay will have a higher value. It will be considerably richer in protein, both because of the higher protein content of legume forage and also because grasses themselves usually contain more protein when grown in combination with legumes. Mixed hay is also higher in calcium and in vitamins than grass hay, and it will usually be more palatable as well. Mixed hay high in the proportion of legumes is best for dairy

cattle, beef cattle, and sheep, while that lower in legumes is most suitable for horses and mules.

Young, actively-growing grass pasture on fertilized fields is good for all classes of stock, even swine or poultry. However, wherever pasture legumes thrive, a combination of grasses and a suitable legume will produce much more feed and over a longer period. Also, the forage will be more nutritious, because of its much higher content of protein, minerals, and vitamins. Grass pasture practically never produces bloat in cattle or sheep, and trouble with bloat from legume pasture may largely be avoided by combining legumes with grass. For swine and poultry, pure legume pasture or a combination high in legumes is generally greatly superior to grass pasture.

563. Grass hay and mixed hay for dairy cattle.—Timothy or other grass hay of the usual quality is much inferior to legume or mixed hay for dairy cows. It is not only of decidedly lower value, but also the cattle will not eat as much of such grass hay as they will of legume hay. Consequently, in order to secure good milk production on grass hay, cows must be fed a considerably greater amount of concentrates than is needed with good legume hay. Grass hay of average quality is unsuited for young dairy calves.

Early-cut grass hay, especially from fields well fertilized with manure or commercial nitrogen fertilizer, can be used successfully as a substitute for legume hay in feeding dairy cattle during the winter. Such timothy or other grass hay will generally be considerably higher in protein than grass hay of the usual sort, and it is also soft and well liked, instead of being harsh, stemmy, and unpalatable.

Unless timothy or other grass hay is early-cut and of excellent quality, the milk yield will be decidedly lower when it is fed to cows as the only roughage than when better hay is fed.[2] This is true even when the ration is balanced with protein supplements. If grass hay is fed in an unbalanced ration, without protein supplements, then the yield of milk will be seriously reduced.[3]

When timothy or other grass hay must be fed to dairy cows without any legume hay, it will give better results if silage is used as part of the roughage. Also, one should be careful to feed a calcium supplement, unless he is sure it is not needed.

When there is a very limited amount of legume hay for the herd, it is best to give the cows one feed of legume hay a day, rather than to feed it more liberally for a time and use it all up during a part of the winter. Foresight is needed to store the various kinds and qualities of hay in the barn so this will be possible.

Feeding some legume hay to cows during the dry period is very important. At this time they have the greatest ability to regain the store of calcium and phosphorus which may have been lost from their bodies during high milk production. (1037)

564. Early-cut versus late-cut grass hay for dairy cows.—The great difference between the value for dairy cows of early-cut grass hay from well fertilized fields and late-cut, poor-quality grass hay has been clearly proved in feeding experiments. In New York trials one group of cows was fed throughout each winter on early-cut, well fertilized timothy hay, along with corn silage and a suitable concentrate mixture.[4] Another was fed good alfalfa hay, corn silage, and a concentrate mixture enough lower in protein to provide the same percentage of protein in each ration. Minerals were added to each ration.

The timothy-hay ration produced as much milk as the alfalfa-hay ration and maintained the live weights of the cows just as well. Also, the cows liked the timothy hay fully as well as the alfalfa and refused no larger proportion, the refuse of both kinds of hay being less than 2 per cent. Similar results were secured in a Wisconsin trial and another New York experiment.[5]

In strong contrast to these results are those secured with late-cut, poor-quality timothy hay in experiments by the United States Department of Agriculture.[6] Cows broke down on the average

in about a year and a half and died or became sterile, when fed such timothy hay and a suitable concentrate mixture, without any pasture but in some cases with a limited amount of corn silage. Because of the lack of carotene in the hay, the calves from cows thus fed were born dead, or else weak and blind. The vitamin content of the milk was so low that it was impossible to raise calves from well-fed cows on the vitamin-deficient milk, unless a vitamin A supplement was added. In contrast to these results, a cow kept on only grain and good timothy hay (United States Grade No. 1) for 4 years gave birth during this period to 3 normal calves.

The cows fed poor-quality timothy hay showed a great desire to steal alfalfa hay from their neighbors fed alfalfa hay, and when they were fed alfalfa in addition, the disasters were prevented. It was surprising that although cows were successfully fed on good alfalfa hay as the only roughage for similar lengths of time, they showed an eagerness for hay of some other kind. The best results were secured when high-quality alfalfa hay and timothy hay were both fed, so the cows could eat as much as they wished of each.

It should be pointed out that the conditions of these experiments were unnatural and most severe, since the cows had no pasture or other fresh green feed at any time. Though poor-quality grass hay is unsatisfactory for dairy cows, it will not produce such disastrous results when fed as the only or the chief roughage during the usual barn-feeding period.

The great differences between early-cut and late-cut grass hay are also clearly shown by New Hampshire metabolism experiments with dairy cows.[7] Timothy hay cut before bloom furnished 44 per cent more net energy than did that cut after the seed had formed. While only about one-third of the protein in the late-cut hay was digestible, about 60 per cent of that in the early-cut hay was digested. When supplied as the only feed, the late-cut hay furnished barely enough nutrients for maintenance, but the early-cut hay supplied sufficient for maintenance and the production of 8 to 10 lbs. of milk a day.

565. Grass hay for beef cattle.—While grass hay of the usual quality is much less valuable than legume hay for beef cattle, such hay will produce satisfactory results when it is properly used. A sufficient amount of protein supplement should be provided to balance the ration, and if little or no legume hay is fed, ground limestone or some other calcium supplement should be supplied.

Grass hay can be used best when fed with a limited amount of legume hay or else with silage. Also, it more nearly approaches legume hay in value for wintering beef cows or stocker cattle than for fattening cattle or for wintering calves. Early-cut grass hay from well-fertilized fields is of decidedly higher value than late-cut hay from worn-out meadows.

When good-quality grass hay is fed to fattening cattle with proper protein and calcium supplements, the gains may be as rapid as with legume hay. However, much more protein supplement will be needed to balance the grass-hay ration and generally more feed will be required per 100 lbs. gain. The grass hay will therefore be worth considerably less per ton than legume hay.

For example, in Oklahoma tests fattening calves fed prairie hay as the only roughage in a properly supplemented ration made as good gains as others fed alfalfa hay, but the prairie hay was worth only 39 per cent as much per ton as the alfalfa.[8] In similar Kansas trials prairie hay, fed along with sorghum silage and grain and supplemented with cottonseed meal and ground limestone, was worth fully two-thirds as much as alfalfa hay.[9]

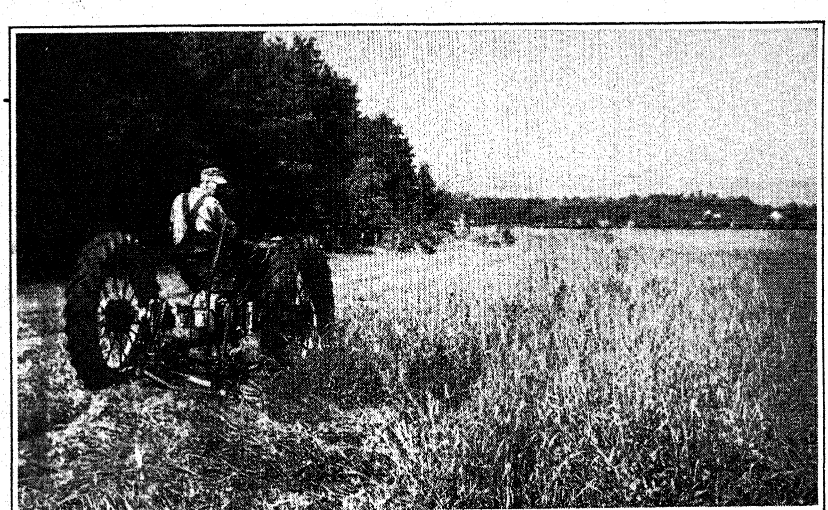
566. Grass hay and mixed hay for sheep.—Pure grass hay is much less satisfactory for sheep than it is for beef cattle, even when supplemented with protein and calcium. Far better results are secured with mixed legume-and-grass hay, or when grass hay is fed along with some legume hay.[10] For example, in an Ohio trial with fattening lambs timothy hay was decidedly inferior to alfalfa hay

as the only roughage, but a combination of equal amounts of the two kinds of hay was only slightly inferior to the alfalfa hay.[11]

Early-cut grass hay is much better than late-cut hay for sheep. Thus, satisfactory results were secured when timothy hay cut in early bloom was fed with corn silage and with 0.8 ounce of ground limestone per head daily and plenty of protein supplement to pregnant ewes in Ohio trials.[12] On the other hand, when late-cut timothy replaced the early-cut hay as the only roughage, the ewes lost weight, became thin and weak, produced lambs lacking in vigor, milked poorly, and showed a decided tendency to shed the fleece because of weakened wool fibers.

567. Grass hay and mixed hay for horses and mules.—For work horses or mules and for light horses, good timothy hay or other grass hay is unexcelled and is taken as the standard with which other hays are compared. Grass hay has this high place in feeding work stock and mature horses in general because it is much less apt to be dusty or moldy than is legume hay. Also, the protein requirements are low for mature horses, except brood mares nursing foals.

For growing colts and for brood mares, well-cured mixed grass-and-legume hay or legume hay is better than pure grass hay, because of its higher content of protein, calcium, and vitamins.



CUTTING A HEAVY CROP OF MIXED TIMOTHY AND LEGUME HAY

Mixed timothy and clover or timothy and alfalfa hay produces a much higher yield and has a greater value for all stock, except horses, than does pure timothy hay. (From New York State College of Agriculture.)

568. Timothy.—In this country timothy (*Phleum pratense*) is by far the most important hay grass and also the most widely-used pasture grass for short-time pasture seedings. It is distinctly a northern grass and does not thrive where the summers are too hot and humid. Timothy is usually seeded in small grain, and a mixture of timothy with clover or alfalfa is commonly used instead of the grass alone. Such a mixture produces a considerably greater yield, and even more important, the mixed hay has a higher value for all classes of stock except mature work horses and mules or light horses.

If conditions are favorable for clover, the first cutting of hay, the year after seeding a combination of timothy and clover, will be largely clover. A still

larger proportion of the second cutting will be clover, for timothy does not produce much second crop, unless cut extremely early. Except in a few districts, most of the clover, especially red clover, dies at the close of the second year. The decaying clover roots then furnish nitrogen for the timothy, so that a larger yield of the grass is obtained the next season than would otherwise be the case. On many farms timothy is regularly used for pasture for a year or more after it has been cut for hay one or two seasons.

A field is often left in timothy for too many years. When this is done, the yield will usually become too low to be profitable, unless the meadow is well fertilized with manure or other fertilizer containing nitrogen, as well as phosphorus. Sometimes farmers continue to speak of hay as "mixed hay" or "clover-and-timothy hay" when practically all the clover has died out, and there is actually only a trifle of clover.

Though numerous experiments have shown that clover or alfalfa hay is greatly superior to the usual kind of timothy hay, timothy continues to be popular for the following reasons: It thrives on soil that is too acid or too poorly drained for alfalfa or red clover. The seed is cheap and generally of high quality. A good stand of timothy is quickly established, and it usually holds well in meadows. The grass seldom lodges, it may be harvested over a longer period than most grasses, and it is easily cured into bright, clean hay which is free from dust and which can be handled with little waste.

Experiments have shown clearly that when quality and yield of hay are both considered, it is best to cut timothy not later than early bloom, for all classes of stock except horses and mules.[13] If the crop is cut later than early bloom, the yield of hay may be a trifle larger, but the quality is much poorer. Also there will be less second growth, which is excellent for late summer and fall pasture. The early-cut grass is a little more difficult to cure than that cut late, but this fact is much more than offset by the higher feeding value of the hay. Continued cutting of timothy before bloom is apt to injure the stand.

For work horses and mules and for saddle and driving horses, hay cut in full bloom is preferable, for that cut too early may be unduly laxative. However, even for horses and mules the cutting should not be delayed much after full bloom, or the grass will become tough and woody. Much more timothy hay is cut too late than too early.

Where fields in the regular crop rotation are used for pasture, timothy is usually the most common pasture grass in the area where it thrives. At early stages of growth timothy pasture is liked even better than bluegrass by stock.

Ordinary timothy is gradually crowded out of permanent pastures by the sod-forming grasses. Pasture-type varieties have therefore been developed which last better in pastures. Varieties have also been bred which are both later and earlier than ordinary timothy.

569. Timothy and timothy-legume hay for horses.—Except for mature horses and mules, mixed timothy-and-clover or timothy-and-alfalfa hay is superior to pure timothy hay or hay from other grasses. For mature horses and mules, timothy hay is the standard roughage with which others are compared. Timothy hay has this high value for such horses and mules because it is usually freer from dust and mold than is legume hay. Also, these animals need but relatively little protein, calcium, and vitamins. Therefore legume hay, which is much richer than timothy in these nutrients, does not have the same advantages for them that it does for dairy cows, growing animals, or sheep. For colts and brood mares mixed timothy-and-legume hay is superior to pure timothy hay, on account of its higher content of protein, calcium, and vitamins.

570. Timothy hay for other stock.—It has been shown earlier in this chapter that early-cut timothy hay from well-fertilized land is a satisfactory hay for dairy cows, when legume hay or mixed hay is not available. (564) On the other hand, late-cut timothy hay or that which

is otherwise of low quality is a poor feed for milk production.

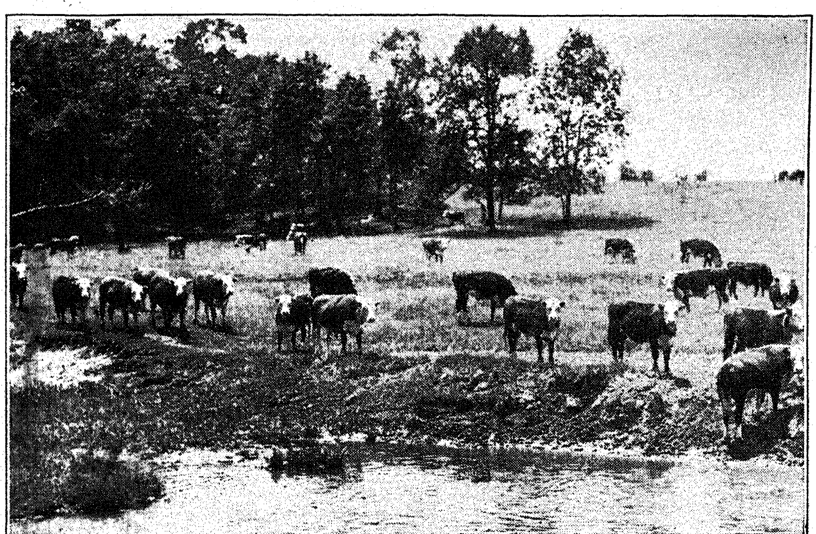
Timothy hay grown on fertile soil and cut early is also much better than ordinary timothy for beef cattle. Steers which were wintered on only timothy hay which had been grown on well-fertilized land gained 1.2 lbs. a day in a Minnesota test, while others fed ordinary timothy gained only two-thirds as much.[14] When ordinary timothy hay is used for beef cattle, one must feed considerably larger amounts of grain and also of protein supplement than are needed with better roughage.[15]

The very unsatisfactory nature of late-cut timothy or other grass hay for sheep has been emphasized earlier in this chapter. (**566**) Though early-cut timothy hay of good quality can be used in sheep feeding, legume hay or mixed hay is decidedly superior.[16]

571. Kentucky bluegrass.—Kentucky bluegrass (*Poa pratensis*), commonly called merely bluegrass or June grass, ranks first as a pasture and lawn grass in the northern half of the United States, except where the climate is too dry. It requires a well-drained, fertile soil, and is not so well suited to wet soils as is red top. The combination of bluegrass and white clover makes an especially good permanent pasture. Therefore bluegrass should generally be grazed closely enough to encourage the growth of white clover.

The fact that bluegrass is one of the richest of grasses in protein helps explain the fondness for it shown by stock. Before heading out in the spring, bluegrass usually contains nearly 20 per cent protein, if dried to a hay basis. Also, when the grass is kept actively growing by proper fertilization and management of the pasture and is not permitted to head out, the percentage of protein will be nearly as high later in the season. On the other hand, bluegrass in bloom or later is low in protein and high in fiber. While bluegrass is much less nutritious at the late stages of growth, even then it is grazed more readily by stock than most other mature grasses.

In Pennsylvania experiments bluegrass at a good pasture stage excelled timothy, bromegrass, orchard grass, al-



BEEF CATTLE FATTENING ON BLUEGRASS PASTURE

In the northern half of the United States, Kentucky bluegrass is by far the most important grass in permanent pastures.

falfa, and Ladino clover in amount of total digestible nutrients or metabolizable energy per pound of dry matter.[17] In Kentucky pasture trials with sheep, bluegrass ranked high among various pastures in daily intake of total digestible nutrients.[18]

Bluegrass starts growth early in spring and soon provides excellent pasturage. It is a cool-weather grass and becomes dormant in hot, dry weather. Therefore it often furnishes but little forage in midsummer. It starts growth again with the coming of fall rains and furnishes first-rate fall pasturage.

There is thus generally a decided shortage of feed on bluegrass pastures in midsummer. Plans should accordingly be made to furnish plenty of other forage at this time by one of the methods discussed earlier. (382) This is especially important in the case of milking cows, or else they will fall off seriously in production. Sometimes a bluegrass pasture is stocked rather lightly in the spring, so there will be some grass left to provide feed later. However, such mature growth is not very palatable or nutritious. Also, if the bluegrass is allowed to grow up in this manner, the shade will tend to kill out the white clover, which is a most valuable part of the best permanent pastures.

Old, run-down bluegrass pasture can be greatly improved through "renovating" it by disking, applying lime and fertilizer, and reseeding to legumes which are suited for pasture in the particular locality. (379) The legume-bluegrass combination will produce considerably more total forage during the season. Still more important, it will furnish much more feed in midsummer.

For swine, bluegrass furnishes excellent spring and fall pasture, but alfalfa, red clover, or rape is far superior in midsummer. Several experiments have been conducted to compare bluegrass with these pastures for swine.[19] Generally, pigs have gained less rapidly on bluegrass than on such pastures as alfalfa, red clover, or rape. Even more important, considerably more grain and other concentrates have been required per 100 lbs. gain by the pigs on bluegrass. In certain tests where bluegrass pasture had a considerable proportion of white clover, it more closely approached the better pastures. Since bluegrass and other grasses are lower in protein than alfalfa, clover, or rape, a somewhat larger amount of protein supplement is needed to balance the ration of pigs fed grain on grass pastures.

Because of its low, spreading growth, bluegrass does not make a good yield of hay. If cut in early bloom, the hay is nearly equal to timothy. However, most bluegrass hay, such as is cut along the roadside after the grass has gone to seed, is of low feeding value.

572. Red top.—Red top (*Agrostis alba*) is suited to a wider range of climate and soil than any other cultivated grass. It ranks next to bluegrass in importance as a pasture grass in the United States. A couple of years after seeding it forms a close, smooth sod, almost as dense as bluegrass. Red top is excellent for damp land, and yet it stands considerable drouth. It endures on poor uplands and on soils too acid for most other grasses, and it may be grown farther south than timothy or bluegrass. It does not respond well to fertilization. Red top is an important hay grass in New England.

Red-top pasture or hay is only fair in palatability. Therefore red top is usually grown only where better-liked grasses do not thrive, and it is commonly seeded with other grasses and the clovers.

573. Bromegrass.—Smooth bromegrass (*Bromus inermis*), usually called bromegrass or merely "brome" in this country, has become one of the most important grasses in the northern and central states for use in legume-grass mixtures for pasture, hay, or silage. (378, 382, 469, 477) It has its highest value in most areas when grown in such a mixture.

Brome is one of the most palatable of grasses and it retains its palatability and nutritive value at much later stages of growth than most grasses.[20] It starts growth early in the spring and continues

well during the summer, because of its drouth resistance. It produces much more aftermath than timothy. Brome will not tolerate continuous close grazing, resembling alfalfa in this respect. It is deep rooted and does best on a well-drained fertile soil.

Bromegrass is slower than timothy to become established after seeding. This is not a disadvantage when it is grown with alfalfa, for it permits the alfalfa to get well started first. When grown alone, bromegrass usually declines greatly in productivity after 3 or 4 years, because of a lack of nitrogen, for it is a heavy feeder. It was formerly thought that this was caused by a "sod-bound" condition, but the vigor of the stand can be restored by applying manure or a commercial nitrogen fertilizer. This condition does not occur when bromegrass is grown with alfalfa, as the legume plants help furnish the nitrogen needed by the grass. Even after the alfalfa dies out, bromegrass continues to thrive for a year or two, because of the nitrogen supply left by the alfalfa.

Bromegrass makes good hay when cut when in bloom or even a little later, but legume-brome hay is, of course, decidedly superior for most stock.

Brome-legume pasture ranks high in yield and value. Even for pigs or poultry, brome alone provides better pasture than most other tall grasses.[21]

Except in the extreme northern part of the United States and in Canada, southern strains of bromegrass developed from Nebraska southward, are decidedly more vigorous and productive than the northern strains. Certain varieties have been developed which spread less vigorously and crowd out alfalfa less.

574. Bromegrass meal.—Bromegrass meal, either dehydrated or field-cured, and made from brome cut before heading, can be used like alfalfa meal as a vitamin supplement for swine.[22] Such bromegrass meal may have as much carotene as alfalfa meal.

575. Orchard grass.—Orchard grass (*Dactylis glomerata*) is a long-lived perennial that grows in nearly every state of this country. It is called cocksfoot in England. Orchard grass does not stand cold winters as well as timothy, but it can endure more heat in summer and does better on soil of low fertility. It is grown most widely in a broad belt south of the middle of the corn belt. Here it is used as a substitute for timothy, and is usually seeded with clover. Ripening two weeks before timothy, it fits in well with red clover. North of this belt, timothy is superior, chiefly because it is hardier and the seed is much cheaper.

Orchard grass grows in bunches or tufts, forming an uneven sod, and hence should be sown with clovers or other grasses, both for hay and for pasture. It does better in partial shade than most grasses and owes its common name to this characteristic.

Orchard grass is used mostly for pasture, especially in combination with a legume, such as alfalfa, Ladino clover, or annual lespedeza. It starts growth early in the spring, is high yielding, endures drouth well, and continues growth late in the fall. It does not stand continuous close grazing, but it is not palatable if it grows up tall, for it becomes very coarse and woody. Therefore the pasture should be stocked heavily enough to keep the rapidly-growing grass from heading out, and it should be clipped, if necessary.

Orchard grass is excellent in a mixture for a pasture which is not too large, and which is to be grazed heavily early in the season. It should not generally be included in a mixture for seeding a large acreage of pasture, for it may then be difficult to get it grazed down in the spring before it becomes unpalatable. In Maryland trials orchard grass-Ladino clover pasture was excellent for beef cattle.[23] Orchard grass is less useful for sheep pasture. In Kentucky tests of several pastures it ranked low in amount of total digestible nutrients consumed daily by sheep.[24]

While late-cut orchard grass makes poor, woody hay, that cut not later than early bloom is equal to timothy. Orchard grass furnishes more second growth than any other hay grass adapted to northern conditions.

Early-cut orchard grass-legume mixtures make good hay-crop silage.

576. Bermuda grass.—In the southern states this sod-forming grass (*Cynodon dactylon*) is the most important pasture grass and also lawn grass. It does not survive northern winters. Common Bermuda grass does not grow tall enough for hay, except on the more fertile soils, but taller varieties have been developed which provide both pasture and hay. Of these varieties Coastal Bermuda grass is most widely grown. It produces more growth in the fall, remains green longer, and is more resistant to leaf spot disease. Suwanee Bermuda grass, another tall-growing variety, is especially well adapted to sandy soil.

Bermuda grass is commonly propagated by planting sprigs (pieces of the rootstalks). Common Bermuda is sometimes seeded, but Coastal and Suwanee produce few viable seeds and must be propagated with sprigs or pieces of sod.

Bermuda grass forms a dense sod but does not provide pasture over so long a season as does carpet grass or Dallis grass. It is late in starting in the spring and ceases growth with the first frosts in fall. Bermuda provides the best pasturage when closely grazed, as otherwise it becomes tough and wiry. It stands drouth well.

If possible, Bermuda should be grown in combination with a legume—lespedeza for summer pasture or crimson clover, white clover, or bur clover for winter pasture when Bermuda is dormant.

Bermuda hay is about equal to timothy in value. By heavy nitrogen fertilization of Coastal Bermuda large yields of hay can be secured, much higher in protein than ordinary grass hay. (372)

577. Prairie grass and hay; wild hay.—The value of native or wild grasses for pasture or hay varies widely in different regions, depending on the climate, the soil, and the kinds of grasses. The native grasses are of especial importance in the western states, where they furnish the chief forage on the ranges and also much of the hay. Among the leading species of native grasses on the western prairies are the grama grasses, the wheatgrasses, the bluestems, and buffalo grass.

The importance of wild hay, including prairie and marsh hay, in the United States is shown by the fact that the acreage of such hay is about two-thirds that of alfalfa. The total amount of wild hay produced is, however, only about one-fourth as great as the production of alfalfa hay, because the average yield is less than 1 ton per acre.

The grasses on the western mountain meadows and on the upland prairies are generally highly nutritious and palatable when actively growing. They then furnish excellent pasturage and also make hay about equal to timothy, when the growth is tall enough to be cut.

On the other hand, grass which has matured may have a very low feeding value, because of weathering and leaching, as has been pointed out previously. (362) Such pasturage may even produce nutritional trouble, owing to lack of protein, carotene, or minerals. If there is little or no rain after the grass matures, there is much less loss through weathering, and the dried mature grass may furnish satisfactory feed, except that it will be low in carotene (vitamin A value).

In certain forest range areas of the southeastern Coastal Plain, tall-growing reeds, or switch cane, furnish most of the feed for beef cattle, even during the winter. North Carolina experiments show the advisability of feeding a protein supplement to beef cows wintered on reed pasture, because the forage is then very low in protein.[25]

Prairie hay cut when still green is similar to timothy hay in composition and feeding value, although usually somewhat higher in protein. Since prairie hay is readily cured and the weather in the prairie region is usually good for haymaking, prairie hay harvested at a reasonably early stage has a good content of carotene. In Oklahoma experiments dairy cows remained healthy when fed continuously for 3 years only good prairie hay with cottonseed meal, which supplies no carotene.[26] In other Oklahoma tests only 8 lbs. of good prairie hay a day

as the only source of carotene was sufficient for normal reproduction.[27]

Prairie hay differs widely in value, however. Arkansas experiments show that sometimes it may be unsatisfactory as the only roughage over long periods.[28]

Much prairie hay or other native hay is cut far too late to have good feeding value. Often it is not cut until late fall when farm work is less pressing. Experiments have shown that reasonably early cutting, not later than mid July, makes much better hay than such late cutting and also usually gives a greater yield, including the aftermath.[29]

The great difference in value of prairie hay due to time of cutting is shown by Nebraska experiments.[30] Beef calves wintered on only prairie hay gained 0.29 lb. a day on hay cut reasonably early, gained only 0.10 lb. a day on hay cut in early August, and lost 0.18 lb. a day on hay cut in September.

Marsh hay is usually decidedly inferior in value to hay from upland meadows, though bluejoint (*Calamagrostis Canadensis*), cut before maturity, nearly equals timothy in value. Marsh hay may often be used satisfactorily for horses and mules, especially those which are idle or not working hard. It is ordinarily not well suited to dairy cattle or sheep. In a recent North Dakota trial in which lambs were fattened on mixtures of chopped hay and concentrates, the gain in weight was satisfactory when chopped marsh hay replaced half the alfalfa hay, but considerably more feed was required per 100 lbs. gain.[31]

The marsh hay of the western mountain districts, though consisting largely of sedges and rushes, is usually of higher value than such hay in the eastern states.

578. Prairie hay for dairy cattle.—In the preceding discussion it has been shown that prairie hay of first-rate quality can be used successfully as the only roughage for dairy cows, even for long periods. In 4 Oklahoma tests good-quality prairie hay (grading as U.S. No. 1, extra green) was compared with No. 1 alfalfa hay as the only roughage for cows fed the usual amounts of concentrate mixture in addition.[32] To balance the ration in protein content, the concentrate mixture in the prairie-hay ration had 20 per cent protein, while a mixture with only 15 per cent protein was fed with the alfalfa hay. On prairie hay the yield of fat-corrected milk was 25.8 lbs. per head daily, in comparison with 26.4 lbs. on alfalfa hay. Taking into consideration the additional cost of the greater amount of protein supplements needed with it, prairie hay was worth on the average 87 per cent as much per ton as the alfalfa hay.

In another Oklahoma test good prairie hay was fairly satisfactory as the only roughage for dairy calves.[33]

579. Prairie hay for beef cattle.—In the western range areas beef cattle are often wintered on prairie hay as the chief feed.[34] Early-cut prairie hay alone will usually furnish plenty of protein for wintering yearling or older cattle or beef cows. When calves are wintered on prairie hay of usual quality as the only roughage, they will need 0.5 to 1.0 lb. of protein supplement per head daily and perhaps a little grain to make as good gains as when fed alfalfa hay alone. In Oklahoma trials prairie hay, properly supplemented, was worth about three-fourths as much per ton as alfalfa hay for wintering calves.[35] In another Oklahoma test it took 1.8 tons of sorghum silage to equal 1 ton of prairie hay in feeding value.[36]

580. Prairie hay for sheep.—Good prairie hay can be used satisfactorily as the only roughage for wintering breeding ewes, if they are fed both protein and calcium supplements.[37] It is decidedly unsatisfactory for wintering ewes or other sheep, when it is the only feed or when fed with grain, without protein and calcium supplements.[38]

Prairie hay, even of good quality, is worth considerably less than legume hay as roughage for fattening lambs, though properly supplemented with protein and calcium. For example, in Minnesota tests, although lambs made satisfactory gains on prairie hay, shelled corn, linseed meal, and ground limestone, the prairie hay was worth only 59 per cent as much per

ton as alfalfa hay.[39] Very unsatisfactory results have been secured when prairie hay was not supplemented with protein or calcium.

Lambs fattened on legume hay as the only roughage will usually make considerably more rapid gains than those fed prairie hay. In Oklahoma experiments the feed allowed lambs on an alfalfa hay ration was restricted a little, so that the gains on prairie hay and on alfalfa hay would be equal.[40] This was done so as to determine the approximate net energy value of prairie hay in comparison with that of alfalfa hay. (**81**) Thus fed, the value of the prairie hay was 87 per cent that of alfalfa hay. When fattening lambs are full-fed for rapid gains, there would, of course, be a greater difference in favor of alfalfa hay.

581. Prairie hay for horses and mules.—Prairie hay of good quality is a first-rate roughage for horses and mules, as it is free from dust and is well liked by them. It can be used in the same manner as timothy hay.

582. The small grains for forage.—In certain regions the small grains are very important forage crops, being used for hay or pasture and occasionally as soiling crops or for silage. In the Pacific Coast states the small grains are important as hay crops, ranking next to alfalfa in acreage. Barley and wheat are the chief grains used for hay in this district, and much hay is also made from volunteer stands of wild oats. The use of straw for feeding is discussed later in this chapter. (**620–624**)

While the small grains are relatively low in protein at a hay stage, they are very rich in protein at the early stages of growth. For example, green rye, wheat, or oats before heading out will contain 20 per cent or more of protein, if dried to the same moisture content as hay. Such young forage is also very rich in carotene and the B-complex vitamins.

583. The small grains for pasture.—In the southern states and also in the prairie winter-wheat district, winter grain is widely used for pasture from fall to spring, whenever the weather is suitable. Farther north, winter grain is a valuable pasture for late fall and early spring, thus extending the usual grazing season. Spring-sown oats or barley are sometimes used for late spring and early summer pasture.

In the North rye is generally superior to wheat for fall and spring pasture, because it is more hardy. Farther south, wheat is preferable in some sections. In the southern states winter oats or barley may be better than rye or wheat for winter pasture. In the portion of the winter-wheat belt from Kansas southward and in the South, winter grain can be grazed moderately from fall to early spring without much decrease in grain yield, if the growth by fall is normal. Sometimes such pasturing even benefits the grain yield, as it prevents lodging. Care must be taken not to pasture the grain when the field is so wet that the stock will injure the crop by trampling.

Winter pasture on small grain or mixed small grain and legumes aids greatly in reducing the cost of milk production in the southern states. Not only does such pasture provide cheap feed, but also the milk yield is increased and the vitamin A content of the milk is kept much higher than when the cows are on permanent pasture in winter or are barn fed.[41]

Green rye of most varieties may give a marked flavor to milk, unless the cows are pastured on it for only 2 or 3 hours after milking. Balbo rye apparently has little such effect.[42]

The importance of winter grain pasture in reducing the cost of beef production is well shown by South Carolina experiments in which rye pasture was compared with sorghum silage as the chief feed for wintering steers.[43] The cost of harvested feeds averaged only 80 per cent as much per head for the steers pasturing rye as for the others. In an Oklahoma test the feed cost of harvested feeds, per 100 lbs. gain, was only 60 per cent as much for lambs grazed on wheat pasture for 2 months and then finished on alfalfa hay and corn, as it was for

lambs fed alfalfa hay and corn in dry lot from the start.[44]

Winter rye and winter wheat provide excellent pasture for swine in late fall and early spring in the northern states, rivalling or excelling bluegrass in this respect.[45] In the central states these winter grains will also furnish considerable forage during the winter, if there has been a good growth by the time cold weather comes on in the fall. In the South winter grains will provide good pasture for swine from fall until spring.[46]

Since young small-grain plants are rich in protein, on the dry basis, such pasture will save protein supplements in the same manner as alfalfa or rape pasture. Pigs on excellent small-grain pasture may make satisfactory gains when fed only corn and minerals. However, it is generally best to add a small amount of an efficient protein supplement, unless the pasture is unusually good.

In the grain-growing districts of the Pacific Northwest, where the summers are dry, ripe small grain is sometimes hogged down, the pigs being turned in when the crop is nearly ripe.[47] In humid districts it is most economical to harvest the crop and feed the threshed grain.[48]

Especially on the grain farms of the West, stubble fields are important in economical pork production. Where the grain is harvested by means of a combine thresher, a considerable amount may be left ungarnered. Many farmers have hog-fenced their fields and turn pigs on the stubble to glean the scattered heads of grain. Gains made on such waste are almost clear profit.

Occasionally, stock grazing winter wheat or oats in the southern plains states are affected by "wheat poisoning." This is similar to or the same as grass tetany, which has been discussed in Chapter VI, where methods of preventing the trouble and a treatment have been suggested. (179)

584. Hay from the small grains.—Well-cured hay from the small grains resembles good timothy hay in composition and feeding value, and it may be used similarly. On the Pacific Coast cereal hay is used extensively for horses and mules. It is satisfactory as the only roughage for mature horses and for wintering beef breeding cows. For dairy cattle, for growing or fattening cattle, or for sheep, it should be fed, if possible, as only part of the roughage, along with legume hay or silage.

A sufficient amount of protein supplement should be used to balance the ration, for cereal hay is low in protein. Also, it is wise to supply a calcium supplement when grain hay is fed as the only roughage, or with such non-legume roughage as corn or sorghum silage or fodder.

Oats or barley make better hay than wheat, though barley hay may sometimes be objectionable because of the beards. Rye hay is least desirable, as it is coarse and lacks palatability.

In the northernmost states, where field peas thrive, a mixture of oats and peas is sometimes preferred to oats alone for hay, as such hay is more palatable to stock and considerably richer in protein. In the South, combinations of small grain with vetch or crimson clover are often used.

The value of hay from the small grains in comparison with alfalfa hay or mixed hay differs considerably, depending on the quality. In some tests oat hay or wild oat hay has been equal or nearly equal to alfalfa hay for beef cattle, while in another trial oat or barley hay was inferior to mixed clover-timothy hay for beef cows.[49] For wintering or fattening calves, a combination of half alfalfa hay and half grain hay is much better than grain hay as the only roughage.[50]

Grain hay should not be used as the only roughage for sheep, except in emergency. In Oregon experiments such a ration resulted in many lambs being born weak.[51] Also, chopped grain hay was inferior to alfalfa hay as the only roughage for fattening lambs.

The small grains should be cut for hay while the leaves and stems are still green, or the hay will be strawlike and low in palatability. In the semi-arid districts good hay can be made at a little later stage of maturity than in humid regions. Small-grain hay cut in the soft-

dough stage was higher in digestible nutrients in tests in eastern Washington than earlier-cut hay, because of the greater proportion of kernels it contained.[52] In humid regions oats and wheat should be cut in the milk stage, except for horses, for which the soft-dough stage is preferred. If rye is used for hay, it should be cut when in bloom. Cereals cut at an early stage cure rather slowly, and therefore care is necessary to get the hay sufficiently dry to prevent heating or molding after it has been stored.

In the semi-arid districts oat hay and other small grain forage have occasionally caused the death of stock from poisoning, because of an accumulation of nitrates in the plants during growth.[53] Most such trouble has occurred in cattle, though losses of sheep and horses have also been reported. (677)

585. The small grains for silage or as soiling crops.—If ensiled not later than the early-dough stage, the small grains make fair to good silage. The addition of about 40 lbs. of molasses or the use of some other preservative may be advisable to improve the quality. The crop should be run through the silage cutter and unusual care is necessary to tramp down the forage in the silo to force the air out of the hollow stems.

A green small-grain crop or such a mixture as oats and peas is satisfactory for feeding green as a soiling crop.

586. Dehydrated young cereals.—A dehydrated product is produced commercially from young oats or other small grain, harvested in the young stage of growth, before it begins to joint. This product, which is called dried cereal grass, or by the trade name of Cerophyl, is high in protein and carotene and rich in B-complex vitamins. It is used in the same manner as alfalfa meal or alfalfa leaf meal, chiefly for poultry.

587. Sudan grass.—Sudan grass (*Sorghum vulgare*, var. *sudanense*) is the most important annual hay grass in the United States. It is a near relative of the sorghums and of Johnson grass and resembles the latter, though it is taller and the leaves are broader and more numerous. However, it is distinctly an annual and entirely lacks the underground stems or rootstocks which make Johnson grass a serious pest in the South.

Sudan grass grows 4 to 8 feet high in cultivated rows, and 3 to 5 feet when sown broadcast. For so rank a grass, the stems are fine, being seldom larger than a lead pencil, and the leaves are soft in texture. It is adapted to the same conditions as the sorghums and is equally drouth resistant, but it is earlier and may be grown farther north. However, it is decidedly a warm-weather grass and does not thrive quite so far north as corn. Sudan grass yields best on fertile, well-drained soil, and needs a liberal supply of nitrogen.

Tift Sudan grass, developed by crossing Sudan grass with a sorghum, thrives better in the South, where leaf diseases affect ordinary Sudan grass seriously. *Sweet Sudan*, another sorghum hybrid developed in Texas, is also more resistant to disease and to chinch bugs. It has sweet stalks and is especially palatable to stock, but starts growth more slowly in the spring than ordinary Sudan grass. These varieties are apt to be higher than common Sudan in prussic acid, which is poisonous.

California No. 23 Sudan grass, popular in California, is taller, coarser, and more vigorous than common Sudan.

Piper, a new variety developed by the Wisconsin Station, has much less prussic acid than other Sudan grasses and is also high yielding and resistant to disease.

Where alfalfa, clovers, timothy, bromegrass, and orchard grass thrive, the chief use of Sudan grass is as a supplementary pasture crop or as an emergency hay crop. Sudan grass surpasses the millets in yield as well as in value of forage in most parts of the United States, and it has therefore largely displaced them there. In the Coastal Plain district of the southeastern states, pearl millet excels Sudan grass. On account of its drouth resistance, Sudan grass is one of the most valuable crops for the western

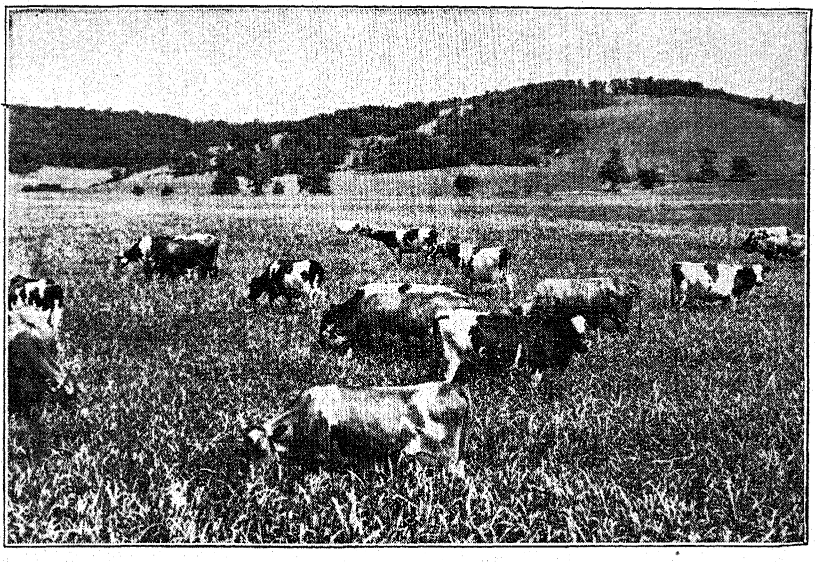
part of the plains region, from central South Dakota to Texas.

Sudan grass is one of the best annual pasture crops, especially to provide feed for the mid-summer period when permanent pastures are usually short. It is therefore particularly valuable for dairy cows, as it provides a large amount of palatable succulent feed at the time when it is often needed to prevent a serious shrinkage in yield of milk. In a good season Sudan-grass pasture should furnish pasturage for about a cow per acre from July for 2 to 3 months.

With Sudan grass of the ordinary variety there is much less danger of prussic acid poisoning than in the case of the sorghums. However, in sections where there is any such danger, stock should not be turned on Sudan grass until it has reached a height of 18 inches to 2 feet, as it then has much less prussic acid.[54]

Short, dark green plants are especially apt to be dangerous, and the second growth usually is higher in the poison than the first growth. Frosted Sudan grass is not more poisonous than before frost, but the new growth afterwards may be high in prussic acid. The crop is higher in prussic acid in regions that are both hot and dry than in moist or cooler climates. Sudan grass rarely has any injurious effect in the southern humid regions or in the northeastern states.

Rotational grazing of Sudan grass is advisable, except in regions where there is no danger of prussic acid poisoning. Each time, the stock should not be turned in until the plants have grown up to a safe height.



SUDAN GRASS FURNISHES EXCELLENT MIDSUMMER PASTURE

Sudan grass furnishes a large yield of palatable pasturage at the time when there is en but little forage on permanent pastures.

Alfalfa, rape, Ladino clover, or red clover is much better than Sudan grass for swine pasture, where these crops thrive.[55] They not only provide more nutritious pasture but also supply forage over a much longer season. However, Sudan grass makes a useful swine pasture where the climate is too dry or otherwise unsuited to such crops. It is therefore especially adapted to the drier portions of the Great Plains, often providing more pasture than alfalfa.[56] Sudan grass is a better pasture crop for pigs over 50 to 75 lbs. in weight than for very young pigs. However, even for young pigs it is better than no pasture at

all. Since Sudan grass is rather low in protein, pigs will not make good gains on it unless fed an efficient protein supplement with their grain.

Sudan grass hay compares favorably with hay from the other grasses in feeding value, but is of considerably lower value than that from alfalfa or clover.[57] It is slightly laxative in nature. Sudan grass hay is satisfactory as the only roughage for horses and mules. For dairy and beef cattle, and especially for sheep, it gives much better results when fed with some legume hay or with silage, than as the only roughage. It has given poor results as the only roughage for fattening lambs, even when chopped and fed with a protein supplement.[58]

Sudan grass is rather difficult to cure into hay, except in the drier regions, for the large stems dry out slowly. It makes the best hay from the time it is heading out until early bloom, but the hay is satisfactory even if the crop is not cut until the seeds are in the dough stage. If Sudan grass is cut early, two cuttings can often be secured, even in the northern states. In the South, it yields 2 or 3 cuttings of hay. The content of prussic acid may not be greatly reduced when the crop is made into hay. It should therefore not be harvested for hay until it has reached a safe stage of growth.

In humid districts mixtures of Sudan grass and either soybeans or cowpeas are often grown, especially for hay. The combination usually yields more than the legume alone, and the hay is more nutritious than Sudan grass hay.

Sudan grass is a good late summer soiling crop. It also makes satisfactory silage, though a crop like Atlas sorghum is superior for silage.[59] In an Illinois trial Sudan grass-soybean silage was not quite equal to corn silage for dairy cows.[60]

Dehydrated Sudan grass meal, made from immature plants harvested at a height of 12 to 24 inches, was satisfactory when used as a vitamin supplement instead of alfalfa meal in Nebraska trials with pigs and in tests with laying hens and chicks.[61] In the experiments with pigs field-cured hay made from similar forage was also tried, but was not so good as the dehydrated product.

588. Bahia grass.—Bahia grass (*Paspalum notatum*), the most common native grass in some of the South American countries, is hardy throughout Florida and along the Gulf Coast. It will grow on drier soils than most other southern pasture grasses, because of its deep root system, and will also thrive on low-lying land. The common type of Bahia grass furnishes little feed in winter, and the seed often germinates poorly.

Pensacola Bahia grass makes more winter growth, thrives farther north, and can easily be established by seeding. The Argentine variety is nearly as frost resistant as Pensacola and is higher yielding. At times it is badly affected with ergot.[62]

589. Bent grasses.—Colonial bent grass, or Rhode Island bent grass (*Agrostis tenuis*), is a common pasture grass in New England and eastern New York, and is found southward to Virginia and westward to the Pacific slope. It thrives on soils too low in lime or too poor in fertility for bluegrass. Like bluegrass, it is a pasture grass, rather than a hay grass. Other species of bent grass are used for lawns and putting greens.

590. Bluestems.—The bluestems (*Andropogon* spp.) are among the most important native grasses of the Great Plains and form a large part of the prairie hay on the Kansas City market.[63] The composition and value of prairie hay and pasture have been discussed previously in this chapter. (577–581)

Both big bluestem and little bluestem, native species, are used to some extent for reseeding range land. Turkestan bluestem or yellow beardgrass, an Asiatic species, is well adapted for reseeding range land in the southern part of the Great Plains.[64] A variety of it is called King Ranch bluestem. Caucasian bluestem is more winter hardy and also more palatable to stock than Turkestan.

591. Buffalo grass.—Buffalo grass (*Buchloe dactyloides*) is a native fine-leaved, sod-forming grass which is the chief species on large areas of the short-grass region of the central part of the Great Plains.[65] It is resistant to drouth, and is well liked by stock. It withstands heavy grazing better than other native grasses there.[66]

592. Buffelgrass.—Buffelgrass (*Pennisetum ciliare*) is a fine-stemmed, deep-rooted perennial grass, recently introduced from Africa, which has proven extremely resistant to drouth on southern Texas ranges. It has

stayed green when even the native grasses dried up.

593. Canada bluegrass.—Canada bluegrass (*Poa compressa*) will grow on thin or poor soil where Kentucky bluegrass fails. It withstands close grazing, stays green during the summer, and makes good pasture, though less leafy and productive than Kentucky bluegrass. It is important on the poorer soils in the northeastern states and in eastern Canada.

594. Carpet grass.—Carpet grass (*Axonopus affinis*) is a perennial, creeping grass that is important as a pasture grass for the southern half of the cotton belt, being especially useful on moist, sandy lowlands. It endures close grazing well and will grow on poorer soils than Bermuda grass, but it is much less productive and nutritious than certain of the recently introduced grasses, such as Dallis grass, Coastal Bermuda grass, or Pangola grass. Though carpet grass forms a dense turf, every effort should be made to keep legumes in it, for such mixed pasture is far better.

595. Dallis grass.—Dallis grass (*Paspalum dilatatum*) is one of the most valuable pasture grasses in the cotton belt, because of its hardiness, the long growing season, and the high yield of palatable and nutritious forage. It is a perennial bunch grass, growing 2 to 4 feet tall, and is especially suited for growing with a legume. Dallis grass has a tendency to lodge and therefore is better for pasture than for hay. It requires a fertile, moist soil, but at the same time is more drouth resistant than Bermuda grass and furnishes pasture over a longer season. It is sometimes difficult to establish because of poor germination of the seed.

Dallis grass is sometimes badly affected with ergot in the seed stage. To avoid possible injury to stock, the grass should be grazed so heavily that it does not head out, or the pasture should be clipped.

596. Fescues.—During recent years two varieties of *tall fescue* (*Festuca arundinacea*) have become important for pasture in certain areas of the United States. These varieties, Alta fescue and Kentucky 31 fescue, are very similar and seem to be adapted to the same conditions.

These tall-growing fescues are long-lived perennials that produce a large yield of forage. They grow best on rich, moist soils and are tolerant of alkaline and saline salts.

Unfortunately, in many areas of our country they are so unpalatable to stock that they have given poorer results than other grasses, even when grown in combination with legumes and when the pasture has been properly managed. The palatability is particularly low if the fescue is allowed to grow up tall. The pasture should therefore be so managed that the fescue does not head out.

Because of the wide difference in the results secured in different parts of the United States, there has probably been more difference of opinion about the usefulness of Alta fescue and Kentucky 31 fescue for pasture than in the case of any other grass. In some experiments stock grazed on mixtures containing tall fescue would eat everything else before they would touch the fescue. In other experiments satisfactory results have been secured with these grasses. Because of the wide difference in the value of Alta fescue and Kentucky 31 fescue for different areas, one should consult his agricultural college or experiment station for advice, before including either in a pasture mixture.

In most of the northern states and in some other places, these fescues have given poor results in comparison with bromegrass, orchard grass, timothy, or bluegrass, because of low palatability.[67] On the other hand, the results have been satisfactory in certain areas of the southeastern states, in some sections of western Washington and Oregon and of northwestern California, and in some other places.[68]

Meadow fescue (*Festuca elatior*) is a tufted long-lived perennial grass which is adapted to wet soils in the northern states. It is grown chiefly in eastern Kansas and western Missouri. It is best as a pasture grass, starting growth early in the season and continuing till late in the fall. As the seed is high-priced, it is usually sown in mixture with other grasses for permanent pastures. Sheep fescue, red fescue, and Chewings fescue are other varieties of fescue sometimes used for pasture.

597. Grama grasses.—The grama grasses (*Bouteloua* spp.) are among the most important native grasses of the western ranges. They are warm-season perennial grasses which are resistant to drouth and grazing and are very palatable to stock. Blue grama is a low, sod-forming grass widely distributed from Arizona to the Dakotas. Black grama is even more drouth resistant and is important on semidesert southwestern grasslands. Side-oats grama is a taller-growing grass which requires more moisture.

598. Guinea grass.—Guinea grass (*Panicum maximum*), the most widely distributed tropical grass, is adapted in this coun-

try only to a narrow strip from Florida to southern California. In the Tropics Guinea grass is used chiefly for pasture, but also it is often fed as a green soiling crop. Guinea grass is a high-yielding, coarse perennial grass which thrives on well-drained soils. It is palatable to stock before it grows up and becomes tough.

In our Gulf Coast region 4 to 6 cuttings a season can be made for a soiling crop. In Hawaii Guinea grass yielded 54 tons of green forage per acre annually, containing 26 per cent dry matter.[69] It was about equal to Napier grass as a soiling crop for dairy cows. In southern Texas on irrigated land it yielded 15 tons of hay per acre a year in 8 cuttings.[70]

599. Harding grass.—Harding grass (*Phalaris tuberosa*, var. *stenoptera*), a relative of reed canary grass, is a very vigorous, long-lived, drouth-resistant, coarse bunch grass which is grown especially in southern California, both under irrigation and on dry land. In California it provides good pasture from October to May, a much longer period than the native range.[71] Like reed canary grass it is not palatable to stock when it grows up tall. In South Australia poisoning of stock sometimes occurs on pasture of this grass.[72]

600. Jaragua grass.—Brazilian jaragua grass (*Hyparrhenia rufa*) is a rather coarse, high-yielding tropical grass which has become important for pasture in certain tropical and subtropical regions. It thrives on well-drained, fertile land and is well grazed by stock if managed so that it does not become tall and unpalatable.

601. Johnson grass.—Johnson grass (*Sorghum halepense*) is a perennial southern grass which is a close relative of the sorghums and of Sudan grass. It is the worst weed of the cotton planter, and yet it is the best meadow grass for some sections of the South. Its vigorous creeping rootstocks make it very difficult to eradicate when once established, and therefore it should never be sown on clean fields.

If cut not later than early bloom, it produces high yields of good hay, and in some of the more fertile areas of the South much Johnson grass hay is produced for the market. Though early cutting reduces the yield somewhat, the feeding value of the hay is enough higher to more than offset the lower yield.[73]

To keep a Johnson grass meadow productive, it is usually necessary to plow and harrow or disc the land about every 3 years. This drastic treatment merely invigorates the Johnson grass. Sometimes an adapted legume is seeded in the Johnson grass to increase the value and to add nitrogen.

Too close continuous grazing reduces the vigor of Johnson grass. Cut at the hay stage, it makes fair to good silage.[74]

602. Love grasses.—Weeping love grass, or African love grass, (*Eragrostis curvula*) and certain other love grasses recently introduced into this country are excellent for controlling water or wind erosion in some sections of the western states. Weeping lovegrass becomes tough and unpalatable when maturity approaches, but is eaten fairly well at early stages of growth. It should generally be seeded only on poor, eroded land where better grasses will not grow or on heavily used feeding areas near the farmstead buildings. Here its tough sod will stand such use.

603. Millets.—The millets are rapid-growing, hot-weather annuals of several kinds and varieties. Of these, the *foxtail millets* (*Setaria Italica*, spp.) are the type grown most commonly for forage in the United States. In this group are common millet, Hungarian millet, and the later-maturing German millet.

In the humid sections the millets are used chiefly as catch or emergency crops, for they may be seeded late and still make a crop of hay. If sown early enough, Sudan grass produces a larger yield of more desirable forage, but the foxtail millets will do better on rather poor land. Soybeans and oats-and-peas also make hay of much greater feeding value. The foxtail millets are especially useful as hay crops on dry-land farms in the northern plains regions.

Millet should be seeded thickly for hay and should be cut just after blooming, or even before this stage. The hay is usually less palatable and inferior in feeding value to timothy hay or even well-cured corn or sorghum fodder.[75] In experiments with fattening lambs, millet hay has not given good results as the only roughage. Millet hay may sometimes cause scouring of stock.

Millet hay is satisfactory for horses if cut early and if fed as only one-third to one-half the roughage. When fed as the only roughage to horses for a long time, millet hay has produced serious lameness and swelling of the joints.[76] This was perhaps due to a considerable amount of millet seed in the hay, as these are said to have a harmful effect on the kidneys.

Japanese millet (*Echinochloa crusgalli*,

var. *frumentacea*), a cultivated, rank-growing variety of common barnyard grass, will grow better in cool regions and on wetter soils than the foxtail millets or Sudan grass. It is taller and coarser than the foxtail millets and may be used as a soiling crop, as hay, or as silage. Japanese millet hay does not apparently have the injurious effect on horses that foxtail-millet hay sometimes does.

Pearl millet (*Pennisetum glaucum*), also called cat-tail millet, is the most widely used summer temporary pasture crop in the southeastern states. Especially in the Coastal Plain area and in Florida, it produces more forage than Sudan grass and is more resistant to disease.[77]

604. Molasses grass.—Molasses grass (*Melinis minutiflora*) is a drouth-resistant perennial pasture grass important in the tropics. It will provide good pasture in areas too dry for Guinea grass. It gets its name from the somewhat sticky leaves.

605. Napier grass, or elephant grass; Merker grass.—Napier grass, or elephant grass (*Pennisetum purpureum*), is a tall, perennial tropical grass which grows 6 to 12 feet high or more in clumps of many stalks about an inch in diameter. It requires rich soil. Napier grass is an important forage crop in Florida and other warm districts of the southern states, because of the heavy yields of palatable forage. Napier grass is usually propagated by means of root or stem cuttings. One should be sure to use a disease-resistant strain.

In the tropics Napier grass is used chiefly as a soiling crop. It may be cut every 3 or 4 weeks during the growing season, but larger annual yields are secured when it is allowed to grow up for about 10 weeks.[78] When it is more mature than this, the digestibility is considerably decreased, and the feeding value is lowered. Under irrigation in Hawaii, Napier grass yielded 71 tons of soiling crop a year, containing 21 per cent dry matter.[69]

Napier grass will not stand close continuous grazing, but under rotational grazing, with periods of 20 to 30 days between grazings, it furnishes excellent pasture over a long season. It makes satisfactory silage if molasses is added and the chopped forage is well packed.

Merker grass, a shorter, more leafy variety of Napier grass, resistant to leaf spot, is widely grown in Puerto Rico.[79]

606. Natal grass.—Natal grass (*Rhynchelytrum rosea*), an annual grass well adapted to poor sandy soils in the Gulf Coast section, volunteers from year to year in many sections. It comes after early crops, and produces late summer and fall grazing or hay.

607. Oat-grass.—Tall oat-grass (*Arrhenatherum elatius*), or tall meadow oat-grass, is one of the common grasses of continental Europe, but it has never become important in this country, largely because of the high cost of the seed, which shatters badly. A non-shattering variety has been developed recently, which should make the seed more plentiful. Oat-grass is adapted to about the same conditions as orchard grass, but will not endure shade. It is usually grown in mixtures with legumes and other grasses for pasture or hay.[80]

608. Pangola grass.—Pangola grass (*Digitaria decumbens*) is a creeping perennial type of crabgrass which is adapted to fertile, well-drained soils in Florida and along the Gulf Coast westward.[81] It is chiefly used for pasture, but makes satisfactory hay if cut early. Pangola grass-white clover pasture was excellent for dairy cattle in Florida tests.[82] Because Pangola grass seeds very sparsely, it is established with runners, plants, or sprigs of green stems.

609. Para grass.—Para grass (*Panicum purpurascens*) is a perennial tropical grass with long creeping stems, which is widely grown in the Tropics. It is adapted to rich, moist soils, will grow well on land too wet for other crops, and will endure flooding for several weeks. Para grass should be grazed rotationally. If managed so that it does not become tall and woody, it is well liked by stock. It is often used as a soiling crop and makes coarse, but good hay if cut at an early stage.

Para grass is propagated by means of cuttings of the runners or pieces of green stems. In the United States it is adapted only to extreme southern areas.

610. Quack grass.—Quack grass (*Agropyron repens*), also called witch or couch grass, is one of the most widely distributed and destructive weeds of the North Temperate Zone. Though quack grass is known chiefly for its bad habits as a weed, when cut in early bloom it makes hay that is said to be equal to timothy, and it furnishes satisfactory pasture. It often forms a considerable part of the "timothy" hay on the market, especially in New England. In permanent pastures it tends to become root bound in 3 to 4 years and often nearly disappears. On account of the great difficulty of eradicating quack grass, it should never be purposely introduced on clean land.

611. Reed canary grass.—Reed canary grass (*Phalaris arundinacea*) is a tall perennial grass with coarse stems and broad leaves which thrives in the northern states on land too wet for other cultivated grasses. It will even grow on land subject to overflow for periods that would kill other grasses. Surprisingly, it stands drouth well on fertile soil. Reed canary grass is high-yielding and grows over a long season, starting early in the spring. It is a good pasture crop if the grass is not allowed to grow above a foot in height.[82] However, it is less palatable than most other pasture plants, and stock should therefore not have other pasture available when grazing reed canary grass. The pasture is better for cattle or horses than for sheep or swine. It should preferably be pastured rotationally, as it will not stand close, continuous grazing.

If cut when beginning to head out, it makes satisfactory hay and may also be used for silage, if a preservative is added. In Wisconsin tests with fattening cattle reed canary grass for silage was worth only one-half as much per ton as corn for silage, considering the feeding value of the silage and also the cost of the preservative for the reed-canary-grass silage.[83]

612. Rescue grass.—Rescue grass (*Bromus catharticus*) furnishes good winter pasture on rich soil in the southern states. It may also be cut for hay. Rescue grass is a short-lived perennial which usually behaves as a winter annual in the South and often volunteers on suitable land after being once seeded.

613. Rhodes grass.—Rhodes grass (*Chloris gayana*), a native of South Africa, is adapted as a perennial only to Florida and a narrow strip in this country along the Gulf Coast to southern Texas and westward to southern California. With irrigation, it has succeeded on soil too alkaline for other crops. It has also given good results in some areas of southern Texas, because it is drouth resistant. It produces good hay, and in central and southern Florida as many as 6 or 7 cuttings may be made in a single season. In tropical countries it is said to be the best hay grass. In Hawaii it was much less productive and less palatable than Napier grass as a soiling crop for dairy cows.[69]

614. Ryegrasses.—Perennial ryegrass (*Lolium perenne*) is a short-lived perennial which is of great importance as a pasture grass in Europe, but it is not grown extensively in this country. Italian ryegrass (*Lolium multiflorum*) generally behaves as an annual, and "domestic ryegrass" in this country is usually a mixture of both varieties and hybrids of them. The ryegrasses are grown principally in the Pacific Coast states and in the southern humid states, and have a wide range of soil adaptability. In the South ryegrass is used principally for winter pasture, usually in combination with crimson or other clover or with a small grain. It makes fine-stemmed, palatable hay when cut at the proper stage.

In a South Carolina experiment ryegrass-crimson clover furnished dairy cattle pasture for an average of 167 days, and produced an average of 3,000 lbs. total digestible nutrients per acre, equivalent to 3 tons of first-rate hay.[84]

615. St. Augustine grass.—St. Augustine grass (*Stenotaphrum secundatum*) is a creeping perennial grass well adapted to muck land in southern Florida. It is commonly used for lawns there and is also a high-yielding pasture grass. As it does not produce seed, it is established by planting pieces of the runners.

At the Everglades Station in Florida St. Augustine grass, grazed by beef cattle, has produced 690 to 780 lbs. of gain per acre and has carried more than 2 animals per acre.[85]

616. Sugar cane; Japanese cane; sugar cane bagasse.—In tropical and semi-tropical regions where sugar cane (*Saccharum officinarum*) thrives, it often produces a larger yield of green forage for cattle than other crops. The forage may be fed as a soiling crop, it may be ensiled, or it may be stored in the fall for several months in large round shocks of about 1 ton each. To avoid waste, the forage should be chopped before feeding. Sugar cane silage or chopped sugar cane which had been stored in shocks made very satisfactory roughage for wintering beef cows in Florida and Georgia tests.[86]

The tops and leaves of sugar cane, removed on harvesting the cane for sugar, also make fair forage for livestock. The amount of leaves and tops ranges from 4 to 8 tons per acre. "Strip cane," consisting chiefly of the leaves and leaf sheaths removed from the stalks at a sugar mill, was fairly satisfactory in a Hawaii test as the roughage for dairy cows when fed green or when ensiled, though inferior to Napier grass.[69]

Japanese cane, a slender-stemmed variety of the common sugar cane, is sometimes grown for forage. In Florida it furnishes good pasture for cattle and hogs from November to March, but is killed by grazing after growth starts in the spring.

Sugar cane bagasse, left at the sugar factories after as much as possible of the juice has been pressed out of the crushed stalks, is extensively used as fuel in the factories. Sometimes the bagasse is dried and the more fibrous parts are used in the manufacture of insulating board or paper. The smaller and more pithy fragments screened out are called *sugar cane pulp* or *pith.* This or the entire ground dried bagasse may be mixed with cane molasses, with or without other feeds in addition, for feeding to horses, mules, or cattle.

In a Hawaiian trial results were not satisfactory when 10 or 20 per cent of sugar cane pith was included in a concentrate mixture for dairy cows, or when 4.5 to 9.0 per cent was added to a ration for chicks or growing cockerels.[87] In a Louisiana trial with beef cattle being wintered, ground sugar cane bagasse was decidedly inferior to ground grass hay, rice straw, or cottonseed hulls, when the roughages were mixed with molasses, cottonseed meal, and minerals.[88]

617. Teosinte.—Teosinte (*Euchlaena mexicana*), a relative of Indian corn, requires a rich, moist soil and is too tropical to have value north of the southern portion of the Gulf states. Teosinte has never become important in the United States, because on moderately fertile soils it yields less than sorghum, and on rich land less than Japanese cane.

618. Wheatgrasses.—*Crested wheatgrass* (*Agropyron desertorum*) is a tall, drouth-resistant, winter-hardy, and long-lived bunch grass, especially well adapted to the northern Plains States and the drier parts of the northwestern states.[89] In these regions it is one of the best grasses for reseeding depleted range land or abandoned crop land. *Fairway crested wheatgrass* (*Agropyron cristatum*), finer-stemmed and more leafy, is used less in the United States, but is popular in western Canada.

Crested wheatgrass furnishes earlier spring and later fall pasture than the native range, and therefore supplements it admirably. It can be used for early grazing in the spring and if the stock is then transferred to native pasture, the wheat grass will grow up for a hay crop. If the moisture supply is sufficient, it will again furnish pasture in the fall. Crested wheatgrass should be cut for hay when it is heading out, or at least by blooming time, for the feeding value and palatability fall rapidly later. Early-cut crested wheatgrass hay is superior to the usual native hay in value.

Slender wheatgrass (*Agropyron trachycaulum*), a short-lived perennial bunch grass which requires somewhat more moisture than does crested wheatgrass, is prevalent in range pastures of the northern Great Plains and the Rocky Mountain region. It starts growth early in the spring and furnishes palatable feed. As it is short-lived, for reseeding it is used with grasses that require a longer time to become well established.

Western wheatgrass (*Agropyron smithii*) is a sod-forming, long-lived grass that forms a large part of the native pastures in the northern Plains States and westward.[90] Resistant to drouth and winter-hardy, it is valuable for reseeding range pasture and for erosion control.

Intermediate wheatgrass (*Agropyron intermedium*), a sod-forming wheatgrass introduced from Russia, is adapted to the same conditions as smooth bromegrass.[91] It is easily established and produces high yields of pasturage or hay.

619. Wild-rye.—Several wild-ryes occur in the native western ranges. Russian wild-rye (*Elymus junceus*), a recently introduced grass, is a deep-rooted, long-lived bunch grass, which has survived drouths that have killed other seeded grasses. Adapted for pasture on a fairly wide range of soils in the northern and central Great Plains and westward, it starts growth early in the spring and the leaves remain green and palatable to stock in summer, when the wheatgrasses are dry and unpalatable.[92]

II. Straw and Chaff

620. Feeding value of straw.—As the small grains and other plants mature, a large part of the more valuable nutrients are transferred from the leaves and stems and stored in the ripening seed. Therefore the straw, which consists of the mature stems and leaves, without the seeds, has relatively little protein, starch, or fat, while the content of fiber and lignin is high. Straw is also low in calcium and phosphorus and in most vitamins, especially in vitamin A value. Probably it generally has considerable vitamin D.

Straw is very much lower in nutritive value than is hay made from the same plants before they have matured. Also, straw is much less palatable than good hay. Because of its high content of fiber and especially of lignin, straw supplies considerably less total digestible

nutrients than good hay, and there is a far greater difference in the amount of net energy.

Straw from the small grains furnishes less than 1 per cent of digestible protein. Therefore this lack of protein must be borne in mind in feeding straw.

Because of its low nutritive value, straw is most useful as part of the ration for animals not being fed for high production. Properly supplemented, it can form a considerable proportion of the feed for wintering beef cows, stocker cattle, or idle horses and mules. It is much less useful for dairy cows, for fattening cattle or lambs, or for calves. Straw is especially unsuited to form a large part of the ration for sheep.

If straw from a combined field has lain in the windrow for several days and become weathered and discolored, the feeding value is poor.

In Europe and Canada pulped roots and meal are sometimes mixed with cut or chaffed straw, and the moist mass allowed to soften. It is then readily consumed by cattle and sheep.

Oat straw with its soft, pliable stems is the most nutritious, followed by *barley straw.* Sometimes barley straw from the varieties with barbed beards may make the mouths of stock sore. *Wheat straw,* being coarse and stiff, is not so readily eaten, and *rye straw,* which is harsh and woody, had better be used for bedding instead of being fed. *Small grain chaff* is somewhat lower in fiber and higher in protein than straw and is a little higher in value, if not loaded with dust, rust, and mold. *Rice straw,* if well cured, may be fed in the same manner as straw from the other cereals.[93]

621. Cereal straw for dairy cattle.—If plenty of better roughage is available, it is best to fill good cows up with more nutritious feed than straw. When there is a shortage of hay or other good roughage but plenty of straw, the straw may be fed once a day in place of one of the feedings of hay. To induce the cows to clean up more straw than they would otherwise eat, it may be sprinkled with diluted molasses. When good straw is used for bedding, some dairymen place the straw in the manger first and allow the cows to pick it over and eat what they will, before putting it under them for bedding.

Oat straw can be used satisfactorily, along with better roughage, in wintering well-grown dairy heifers, if plenty of protein supplement is provided. For example, in a Wisconsin trial dairy heifers made nearly as good gains on oat straw, corn silage, and 3 lbs. of a protein-rich concentrate mixture as others fed alfalfa hay, corn silage, and only 2.5 lbs. of a concentrate mixture consisting chiefly of ground corn.[94]

622. Cereal straw for beef cattle.—Straw from the small grains is satisfactory as the chief feed or even as the only roughage for wintering beef breeding cows or young cattle over a year of age, if it is properly supplemented. On the other hand, straw is too low in nutrients to form any considerable part of the ration for fattening cattle.

In the wheat-growing districts of the West, beef cows are frequently wintered on straw as the only roughage. Montana and Oregon trials show that cows in medium to good condition in the fall can be wintered satisfactorily on 12 to 20 lbs. of straw daily plus 1 lb. of cottonseed cake or meal or other protein supplement, or on straw and 4 to 5 lbs. of alfalfa or other legume hay.[95] It is very important to feed about 1 lb. per head daily of a high-protein supplement and also to supply a calcium supplement when cows are wintered on straw as the only roughage, or when fed straw with other non-legume roughage. Unless the cows have had good green pasture in the fall and consequently have a store of vitamin A in their bodies, alfalfa meal or another vitamin A supplement should be fed.

If beef cows are in good condition in the fall and the winter is mild and not too long, they can even be carried through the winter on straw alone. However, they will then lose 50 to 200 lbs. per head and may not be thrifty enough in the spring to provide sufficient milk for their calves. Such an inadequate ra-

tion should therefore be used only in emergencies.

If there is a shortage of better roughage, straw can replace part of the hay or silage usually fed fattening cattle. In such cases care must be taken that the other feeds supply sufficient protein, calcium, phosphorus, and vitamin A value. Provided the ration is properly supplemented with protein and also with calcium if needed, cattle that are full-fed on grain with a liberal amount of silage or wet beet pulp may make nearly as rapid gains with straw for the dry roughage as when fed legume hay.[96] The actual value of the straw per ton will, of course, be much lower than that of the hay, because of the larger amount of protein supplement needed with the straw.

Fair gains can even be produced on cattle a year old or more with straw as the only roughage, if a liberal amount of grain is fed and protein and calcium supplements are provided.[97]

Straw is not well suited for use as part of the roughage for fattening calves or even for wintering calves to be fattened later.[98]

623. Cereal straw for sheep.—Straw should not be fed as the only roughage to sheep, as it is too low in nutrients, especially protein, calcium, and vitamins. Moreover, it is constipating. If hay is scarce or high in price, a limited amount of straw can be used along with legume hay and silage for breeding sheep or fattening lambs.

Straw is unsatisfactory as the chief roughage for wintering breeding ewes, even when fed with a small amount of silage and plenty of protein supplement and minerals. Straw also gives very poor results as the only dry roughage for fattening lambs.[99] Feeding a mixture of half chopped barley straw and half chopped alfalfa hay with barley grain to fattening lambs was much less profitable in a California test than a ration of alfalfa hay and barley, without the straw.[100]

When sheep are to be fed such unpalatable roughage as straw, along with good legume hay, it is best to feed the straw in the morning and the better-liked hay for the evening meal.

624. Cereal straw for horses and mules.—Little or no straw should be fed to hard-worked horses or mules, for it is too poor in digestible nutrients and net energy. On the other hand, animals that are idle or at light work may be wintered largely on bright straw, instead of more expensive hay.[101] This will greatly reduce the cost. However, work stock should not be wintered on straw or stover only, for they are too low in protein, in calcium and phosphorus, and even in digestible nutrients to be the only feed, even for idle horses.

In many districts of Europe horses are fed cut straw mixed with their concentrate allowance, small amounts being thus utilized even for horses that are at hard work.

625. Straw from other plants.—When timothy, red top, or other grasses are raised for seed, the threshed *grass straw* can often be used for feeding in the same manner as cereal straw. When fed as the only roughage, wheatgrass straw and giant bluegrass straw were much less palatable than alfalfa hay to fattening lambs in a Washington test.[102]

Flax straw is about equal to oat straw, when of good quality. South Dakota experiments show that it can be used satisfactorily as the only roughage for wintering beef breeding cows or yearling steers.[103] Flax straw that has considerable green, immature flaxseed must be fed with great caution, as it may contain poisonous amounts of prussic acid.[104] Volunteer flax which sometimes springs up in the fall is very unsafe for pasturing.

Buckwheat straw is of low value and may cause digestive disturbances if fed in large amounts.

626. Straw pulp.—During serious shortages of grain and other concentrates for stock feeding, methods have been used in Europe to increase the digestibility of straw by treatment with a dilute solution of caustic soda (sodium hydroxide). In the older process, developed in Germany, the straw was digested at a high temperature under pressure. In a method tested in England during the

recent World War, straw was digested for 12 to 22 hours with a cold 1.5 per cent solution of caustic soda in an open tank. After digestion, it is necessary to wash out the caustic soda thoroughly from the treated straw pulp with running water, or by repeated washings.

Through the action of the caustic soda, some of the fiber and other resistant carbohydrates in the straw are partially hydrolyzed, or digested. Farm animals can therefore digest the straw pulp much more completely than the untreated straw. Such treated straw was found to have as high a starch value, or net-energy value, as good hay.[105]

In English feeding experiments with straw pulp the results differed rather widely, but in most tests it had a considerably higher value than untreated straw. Because straw is very bulky, considering the feeding value, so much labor was required in treating straw that the method was not used to any considerable extent in England. In certain large dairies in Sweden, larger-scale, semi-automatic equipment was developed which made such a method of practical value in time of feed shortage.[106]

QUESTIONS

1. Why should a mixture of grasses and legumes ordinarily be used for permanent pasture or meadows?
2. Compare the composition and nutritive value of grasses at various stages of growth.
3. Discuss the use and value of grass hay and mixed hay for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules.
4. How can grass hay be made that is satisfactory for dairy cows?
5. Why is timothy the great hay grass of the northern United States, and in what respects is it inferior to legumes? When should it be cut for hay?
6. What are the advantages of seeding a mixture of timothy and clover or timothy and alfalfa in comparison with seeding timothy alone for hay?
7. Why does Kentucky bluegrass rank first as a pasture grass in most of the northern half of the United States?
8. Under what conditions is red top chiefly grown?
9. Why has bromegrass attracted much attention recently in the northern and central states?
10. What are the characteristics and value of orchard grass?
11. Discuss the importance and use of Bermuda grass.
12. What is the composition and relative value of good prairie hay; of marsh hay?
13. If prairie hay is important in your district, discuss its use and value for: (a) Dairy cows; (b) beef cattle; (c) sheep; (d) horses and mules.
14. Of what importance are the small grains for forage in your district; in other sections of the United States?
15. What are the characteristics of Sudan grass? Discuss its value for hay; for pasture.
16. State the characteristics and value of 4 other grasses which are important in your district.
17. Discuss the composition of straw, and state how it may be best used in stock feeding.

CHAPTER XIX

ROOTS, TUBERS, AND MISCELLANEOUS FORAGES—POISONOUS PLANTS AND POISONOUS FEEDS

I. Roots and Tubers

627. Roots unimportant for livestock in the United States.—In the United States the acreage of roots raised for feeding livestock is insignificant in comparison with that of other forage crops. On the other hand, in northern Europe extensive use of roots is made for stock feeding.

This great difference is due chiefly to the difference in the climate. Northern Europe with its cool summers is well adapted to the growing of roots but not to the raising of corn. In most parts of our country the summers are hot, and corn or the sorghums thrive, furnishing in the form of silage a palatable succulent feed which is much cheaper than roots. Also, root crops require much hand labor, and labor is cheaper in Europe than in this country.

In the United States the growing of roots for livestock is advisable only under certain very special conditions. Roots may be used as a substitute for corn silage where the summers are too cool for corn, though hay-crop silage is generally a much more economical source of nutrients. Sometimes roots are fed as a relish to animals being fitted for show or to cows on official test. Occasionally, roots are grown to supply succulent feed for poultry in winter. However, most roots do not replace alfalfa meal as a vitamin supplement, and poultrymen have therefore largely discontinued their use.

While the acreage of root crops grown for stock feeding in the United States is very small, the production of sugar beets for sugar manufacture is of importance in certain sections, particularly in Colorado and other western Mountain States. The by-products from this industry—beet tops, beet pulp, and beet molasses—are used for stock feeding. Also, cull and surplus potatoes and sweet potatoes are important by-product feeds in certain sections.

628. Composition and value of roots and tubers.—All roots and tubers are very watery and low in dry matter. Especially so are mangels, turnips, and rutabagas, which have only 9 to 11 per cent dry matter. This is less than half the percentage of dry matter in corn silage. However, the dry matter that roots and tubers do contain is of high quality, being low in fiber, highly digestible, and high in net energy per pound. Roots and tubers are therefore more like watery concentrates than like roughages. For convenience, they are grouped with green roughages in the Appendix Tables of this book.

The chief nutrients in roots and tubers are carbohydrates—largely cane sugar in beets and mangels, and starch in potatoes. Roots and tubers are low to fair in protein content, are low in calcium, and are only fair in phosphorus. Carrots and sweet potatoes are rich in carotene, but other roots and tubers have little or no vitamin A value. Roots or tubers do not supply vitamin D. They are low in riboflavin, but are quite high, on the dry basis, in niacin.

Roots and tubers are therefore decidedly different from legume hay or other legume forage, which is rich in protein, in calcium, and in carotene, and rather high in riboflavin. Also, field-cured hay from legumes or other crops is an important source of vitamin D in the winter feeding of all stock except poultry, while roots and tubers do not supply this vitamin.

Although roots cannot replace legume hay in stock feeding, they can be

used as a substitute for a considerable part of the grain customarily fed to dairy cows or to fattening cattle and lambs. This is usually not economical in the United States, but is a common practice in northern Europe. In most of the trials with dairy cows a pound of dry matter in such roots as mangels, sugar beets, or rutabagas has been equal to a pound of dry matter in grain, such as corn, wheat, or barley, or at least equal to a pound of these grains.[1]

breeding cattle and sheep in thrifty condition.

When roots are fed to stock in this country, cattle are not usually fed more than 20 to 30 lbs. per head daily, fattening lambs not more than 4 or 5 lbs. and breeding ewes 2 to 3 lbs. In Europe much greater amounts are often fed.

Roots should be chopped or sliced before feeding, when there is any danger of livestock choking on them. Any undue amount of dirt should be removed before the roots are chopped. Often the grain or concentrate mixture is sprinkled over the chopped roots. Cooking or steaming roots or tubers is a waste of labor and fuel, except that potatoes should be cooked for swine and poultry. In Europe, roots for fattening cattle are often pulped and spread in layers, alternating with layers of cut hay or straw. After being shoveled over, the mass is allowed to stand several hours before feeding, to moisten and soften the straw or hay. In this manner considerable straw may be utilized.

SUGAR BEETS IN A WESTERN IRRIGATED DISTRICT

While but relatively few acres of sugar beets are grown for stock feeding in this country, the raising of sugar beets for the beet sugar factories is an important industry in certain sections, especially in some of the irrigated districts of the West. (From U.S. Reclamation Service.)

Because such roots as mangels, rutabagas, and turnips contain less than half as much dry matter as corn silage, they are worth much less per ton for stock feeding. Experiments have shown that for dairy cows 100 lbs. of corn silage are worth more than 200 lbs. of these roots. For fattening lambs it has required, on the average, 145 lbs. of roots to replace 100 lbs. of corn silage.

In addition to the nutrients they furnish, roots and other succulent feeds have a beneficial effect upon animals and are highly esteemed for keeping

For winter feeding in the northern

states roots must be stored in well-ventilated pits or cellars, but in mild climates they may remain in the field until fed. In experiments in Ireland, mangels lost about 27 per cent of their dry matter during 5 months' storage, because of the respiration which is continuously taking place.[2]

The root crops most commonly grown for stock feeding are mangels, rutabagas, and turnips. Sometimes sugar beets, carrots, parsnips, or potatoes are raised especially for this purpose.

629. Roots vs. silage.—It costs considerably more to grow an acre of roots than to grow an acre of corn and ensile it, because root crops require more thorough preparation of the soil and far more hand labor in cultivation, harvesting, and storage. Also, experiments have shown that where corn thrives it yields much more dry matter per acre than the best root crops. As a result of the greater cost in growing roots and their lesser yield of nutrients per acre, corn silage will furnish digestible nutrients at half the cost of roots in good corn-growing sections.

Occasionally, some persons get an incorrect idea of the economy of root crops, because of the very large tonnage sometimes produced. Under very favorable conditions such root crops as mangels, sugar mangels, or rutabagas may yield 20 to 30 tons per acre or even more. This is a far greater fresh weight than is secured in corn silage, but the roots are so watery that the corn crop will yield a much larger amount of dry matter and digestible nutrients per acre.

In localities in this country where the growing season is too short or the weather too cool for corn, hay-crop silage will generally supply succulent feed at decidedly less cost than root crops.

630. Roots for dairy cattle.—Roots are an excellent feed for dairy cattle, but they are so uneconomical in this country that they are rarely fed. Roots may be a useful feed where a dairyman does not keep sufficient stock so that he can feed silage fast enough to keep it from spoiling, or if a silo is not available. Years ago roots were widely used for cows on official test, where the object may be maximum yield of milk rather than low cost of production. However, soaked beet pulp is now generally used in place of roots, because of the greater convenience. Like silage and soaked beet pulp, roots are believed to have a "cooling" effect on the digestive system, helping to prevent digestive trouble when cows are heavily fed on concentrates.

Experiments have shown that adding roots to a palatable ration containing corn silage tends to increase the yield of milk and fat slightly.[3] This is doubtless because roots are so well liked by cows that their feed consumption is greater when roots are fed. However, the increase in production is not large enough to offset the cost of the roots, with milk at usual prices.

In feeding trials with dairy cows the dry matter of corn silage has been as valuable or nearly as valuable as that in roots.[4] Since roots have much less dry matter than corn silage, they are worth correspondingly less per ton. For example, it requires about 3.0 tons of mangels, 2.5 tons of rutabagas, or 1.7 tons of sugar beets to furnish as much dry matter as in 1 ton of good corn silage. These figures therefore represent approximately the amounts of root crops it takes to equal a ton of corn silage for milk production.

When roots are fed to dairy cows as the only succulent feed in place of corn silage, the production of milk and fat will be about as high and perhaps even slightly higher than on corn silage. However, in good corn-growing sections, the production on the silage ration will be much more economical.[5] Compared with root crops, silage of the kind that can be produced in Great Britain, where corn does not thrive, has given varying results. In some trials the production has been more economical on roots than with silage made from such mixtures as oats with peas or vetch, and in other tests the silage ration has been cheaper.[6]

631. Roots for beef cattle.—Although roots are rarely fed to beef cattle in this country, they are extensively used

for this purpose in Great Britain and other northern European countries where corn does not do well. Sometimes fattening cattle are given all the chopped or sliced roots they will clean up, along with a limited amount of concentrates and hay or straw. The hay or straw is often chopped and mixed with the roots. By this means the cattle may be induced to eat considerable straw or poor hay. Because of the high water content of roots, the amounts eaten are surprisingly large. Often cattle 2 years old or over will eat 80 to 100 lbs. of roots per head daily, if fed all they will take. When cattle are fed only 40 to 60 lbs. of roots a day with a greater amount of other feeds, the gains will be as good as when the maximum amount of roots is supplied. In this system of fattening cattle much less grain is used than in our country, but good gains and carcasses of excellent quality are produced.

In Canadian trials corn silage was worth considerably more per ton than roots, because of its much greater content of digestible nutrients.[7] When only a few pounds per head daily of roots are fed to cattle as an appetizer, they may be worth as much, pound for pound, as corn silage.[8]

632. Roots for sheep.—Roots are an excellent succulent feed for sheep, but in the United States silage is usually much more economical. Because such roots as rutabagas, turnips, and mangels are far more watery than corn silage, it has taken about 145 lbs. of roots to equal 100 lbs. of corn silage in experiments with fattening lambs.[9]

Some shepherds have believed that roots are preferable to corn silage for breeding ewes. However, in 4 Wisconsin experiments the percentage of strong lambs was noticeably higher when ewes were fed corn silage as part of the roughage in a well-balanced ration, than when rutabagas replaced the silage.[10] In these trials rutabagas were worth only about two-thirds as much per ton as corn silage, not considering the better lamb crops from the ewes fed silage. Rutabagas were also less valuable than corn silage for wintering ewe lambs.

In Great Britain roots are widely fed to sheep of all classes. Sometimes fattening lambs are fed as much as 15 to 20 lbs. of rutabagas or other roots per head daily, though much smaller allowances are more common. In this country it is unusual to feed more than 4 to 5 lbs. of roots per head daily to fattening lambs, and even half this allowance, preferably chopped, will furnish enough succulence in the ration. When pregnant ewes are fed too much roots, weak lambs sometimes result, probably due to a lack of protein or minerals in the ration. The allowance of roots had therefore best be restricted to 2 or 3 lbs. per head daily, and good hay should be fed in addition.

Some believe feeding mangels or sugar beets to sheep over long periods may tend to produce calculi, or stones, in the kidneys and bladder, which are dangerous in the case of rams and wethers. The roots may not be the primary cause of the trouble, however, as calculi occur when sheep are fed no roots.[11]

633. Roots for horses.—Occasionally roots, especially carrots, are fed to horses in this country as an appetizer or an aid to digestion, where cost of keep is not considered. Hard-worked or driving horses should not be fed large allowances of roots. Some advise feeding no roots to brood mares for a few weeks before and after they foal.[12]

634. Roots for swine.—Roots were formerly esteemed by many swine raisers, especially for feeding brood sows. However, in Wisconsin experiments with brood sows and fattening pigs, when roots were added to efficient rations containing legume hay, the roots had so low a value that they were very uneconomical.[13] In no case did the addition of roots result in the sows having larger or more thrifty pigs.

In these trials alfalfa or clover hay was a much more efficient addition than roots to the rations of brood sows or fall pigs. We might expect this, since legume hay is rich in good-quality protein, in calcium, in carotene, and in vitamin D, and it also has a desirable laxative

effect. Roots are palatable, succulent, and laxative, but they are low in protein and in calcium. Moreover, roots are lacking in vitamin D, and roots, except carrots, have little or no carotene (vitamin A value).

In experiments conducted many years ago in which roots were added to inefficient, old-time rations for pigs, 448 lbs. of roots, on the average, saved 100 lbs. of concentrates.[14] However, roots have a decidedly lower value than this for swine when added to modern well-balanced rations which include some legume hay as a vitamin supplement.

635. Roots and other succulent feeds for poultry.—Some years ago it was considered nearly essential to supply succulent feeds to hens in winter to secure maximum egg production. This has been entirely changed by the efficient dry rations that have been developed through the discoveries in poultry nutrition.

When modern rations are used which provide a plentiful supply of vitamins and meet the protein and mineral requirements fully, poultry produce excellent results during the winter without fresh green feeds or other succulent feeds. The practice of growing cabbage or roots especially for poultry has therefore been largely discontinued.

When green feeds and other succulent feeds are available for poultry, there is no question but that they are excellent additions to winter rations. Therefore, such green feeds as cull or waste cabbage or other vegetables should be fully utilized. Where cabbage is raised for market, the small, unmarketable heads make a cheap feed for poultry. The cabbage heads should be suspended by a string about 18 inches from the floor, so that the birds can reach them easily. A good method of feeding mangels or sugar beets is to split them lengthwise and stick the halves on nails driven in the walls of the hen house, about 18 inches from the floor, and then let the fowls pick at them.

636. Potatoes.—In the United States other crops excel potatoes (*Solanum tuberosum*) for feed production, and therefore only cull or surplus potatoes are generally fed to stock. On the other hand, in some sections of Europe heavy-yielding varieties of large-sized potatoes are often raised for stock. (The use of dehydrated potatoes for feeding is discussed in Chapter XXIII.)

Potatoes contain about twice as much dry matter as rutabagas or carrots. However, they are more watery than many realize, for they have less dry matter and less total digestible nutrients than well-eared corn silage. They are rich in starch, on the dry basis, but are only fair in protein. They are deficient in vitamins A and D. These lacks are made good when potatoes are fed with well-cured legume hay.

Potatoes are satisfactory for feeding to dairy cows, beef cattle, sheep, horses, swine, and poultry in limited amounts as a substitute for grain or other low-protein feed. It takes about 400 to 450 lbs. of potatoes to supply as much total digestible nutrients as there are in 100 lbs. of grain, and this is approximately the value of potatoes as a substitute for grain in stock feeding. Stated in another way, 100 lbs. of potatoes are worth about 22 to 25 per cent as much as 100 lbs. of grain.

Potatoes should be cooked for swine and poultry, but this is not necessary or profitable for other stock. It has been generally recommended that potatoes should be chopped before feeding to cattle or sheep, to make them more palatable and avoid choking. However, in recent Minnesota trials fattening cattle seemed to prefer whole to sliced cull potatoes.[15] Stock should be accustomed to potatoes gradually, as they are not very palatable. Feeding too large amounts of raw potatoes may cause scours.

Unripe potatoes and especially the sprouts of stored potatoes contain small amounts of solanin, a poisonous compound. It has therefore been advised that in feeding badly-sprouted potatoes the sprouts be removed. In trials at the North Dakota Station, however, when dairy cows were fed for considerable periods on reasonable quantities of sprouted, sunburned, or decomposed potatoes, and even on potato sprouts, along with other feeds, there was no injurious effect.[16] Nevertheless, because of reports of stock being injured by excessive amounts of potatoes, it is not wise to let them have access to an unlimited amount of either good or poor-quality potatoes.

637. Value and use of potatoes for various classes of stock.—For dairy cows potatoes were a satisfactory substitute for corn silage in Idaho and North Dakota trials, be-

ing nearly equal to silage in value per ton when 24 to 40 lbs. were fed per head daily.[17] However, the potatoes were not so palatable as silage, and the cows seemed to lose their appetites for potatoes after several months. Fed in such quantities, potatoes did not affect the flavor of the milk or the odor of the milk or butter, but milk or cream exposed to an atmosphere heavy with potato odor readily took it up. Potatoes should therefore be fed immediately after milking and not before.

When a large allowance of potatoes was fed to cows in Vermont tests, the potatoes were not equal to the same weight of dry matter in corn silage, and the butter was soft.[18] If potatoes are fed in a properly-balanced ration they do not dry up cows, as is sometimes believed.

Cull potatoes have been used satisfactorily in place of corn silage for fattening beef cattle and beef breeding cows.[19] For fattening cattle cull potatoes were worth about 80 per cent as much a ton as corn silage, or twice as much per ton as rutabagas. In Minnesota trials good gains were made by yearling steers fed cull potatoes, oat straw, protein supplement, and a little grain.[20] Oat straw was better for feeding with potatoes than legume hay, as it counteracted the laxative effect.

Cull potatoes are satisfactory as part of the ration for fattening lambs or for wintering breeding ewes.[21] In 12 comparisons with fattening lambs the addition of cull potatoes to a ration of grain and legume hay, with or without a protein supplement, has usually increased slightly the gains of the lambs. In these trials one ton of potatoes was equal in feeding value, on the average, to 199 lbs. grain and other concentrates plus 447 lbs. alfalfa hay. With hay valued at half the price of grain per ton, cull potatoes would be worth 21 per cent as much per ton as grain.

Horses and mules may be fed potatoes, cooked or raw, in amounts up to 15 or 20 lbs. per head daily.

In English experiments when cooked potatoes were fed to pigs as a partial substitute for grain in well-balanced rations, it required about 410 lbs. of potatoes (weighed before cooking) to equal 100 lbs. of grain and other concentrates.[22] In South Dakota and Washington tests cooked potatoes had a slightly higher value than this when added to properly-balanced rations.[23] For the best results in swine feeding, the proportion of potatoes should not be greater than 4 lbs. of potatoes to each pound of concentrates. It is best to add salt to the water in which the potatoes are cooked, to increase the palatability. The potatoes should be cooked thoroughly, and the water in which they are cooked should be discarded, as it is not palatable. Raw potatoes generally produce poor results when fed to swine.[24]

Boiled or steamed potatoes are a satisfactory substitute for part of the grain for poultry. The cooked potatoes, after being mashed, may be mixed with an equal weight of the regular dry mash and fed as a warm, moist mash. When potatoes are added to the ration, it must be borne in mind that they are very low in protein, and that they do not supply vitamin A value. In Ohio experiments it required 410 to 467 lbs. of cooked potatoes (weighed before cooking) to replace 100 lbs. of dry mash in feeding broilers, growing pullets, and laying hens.[25]

Because of the great shortage of grain and other concentrates for livestock feeding in Europe during the recent war, potatoes were used extensively as a considerable part of the rations for poultry. The results were good when care was taken to supply sufficient vitamins and protein in the potato rations.[26]

The value and use of dried or dehydrated potatoes are discussed in a later chapter. (981)

638. Potato silage.—Experiments show that satisfactory silage can be made by running a combination of potatoes and hay or dry corn or sorghum fodder through the silage cutter.[27] It is best to add 20 to 25 lbs. of dry forage to each 100 lbs. of potatoes, but even 10 lbs. may produce satisfactory silage. The dry forage absorbs most of the excess moisture of the potatoes, and the combination goes through the proper silage fermentation. The silage is eaten readily by stock and is approximately equal to corn silage in value per ton. For dairy cows the allowance had best be limited to about 40 lbs. daily per 1,000 lbs. live weight. Silage made from raw potatoes is not satisfactory for swine or poultry.

A silo for potato silage must be very well reinforced to stand the pressure of the heavy material, and it should have drains to allow the escape of surplus juice. Stones taken up with the potatoes in harvesting may often damage the knives of the silage cutter.

Chopped raw potatoes alone do not make good silage, and satisfactory silage may not be produced when 2 to 3 per cent by weight of ground corn is added as a preservative. On the other hand, well-steamed potatoes can be successfully ensiled. This method has been used considerably in Germany, but

under usual conditions it would be much simpler and more economical to ensile potatoes with hay or other dry forage. In an experiment in Norway steamed potato silage or steamed potatoes satisfactorily replaced part of the grain for feeding bacon pigs.[28]

Potatoes can also be mixed with green corn or sorghum fodder or a green hay crop as it is ensiled. It is best to use not more than 500 lbs. of potatoes with each ton of green fodder.

639. Sweet potatoes.—Sweet potatoes (*Ipomea batatas*) are a southern root crop which is raised chiefly for human food. Recently considerable acreages have been used for starch manufacture and for the production of dried sweet potatoes for stock feeding. (The value of dried or dehydrated sweet potatoes is discussed in Chapter XXIII.) Each year several million bushels of cull or unmarketable sweet potatoes from crops grown for table stock are available for feeding in the South, and some are grown primarily for feeding livestock.

SWEET POTATOES PRODUCE A LARGE YIELD PER ACRE

In the southern states sweet potatoes yield more dry matter per acre than does corn grain. However, the cost per acre of growing sweet potatoes is considerably greater.

In this Alabama field of sweet potatoes the vines have already covered the field. (From Ware, Alabama Station.)

In the southern states sweet potatoes will produce more dry matter and a greater feeding value per acre than corn grain, but the cost is considerably higher per acre in growing sweet potatoes, because of the greater amount of labor required. The average acre yield of sweet potatoes in this country was 93.6 bushels, weighing 55 lbs. each, for the 10-year period 1945–1954. Much larger yields are secured under good conditions in the chief producing sections. In 3-year tests at 8 locations in the South the average yield was 225 bushels per acre.[29]

Sweet potatoes are high in dry matter for a root crop, averaging 31.8 per cent, and they are rich in starch, but they are extremely low in protein. They are also low in calcium and phosphorus. These lacks must be borne in mind in feeding them. Sweet potatoes are high in carotene, and the deeper-colored varieties are much richer than those lighter in color.

Chopped sweet potatoes are a good feed for dairy cows and can be used as a substitute for corn or sorghum silage, or in place of part of the grain ordinarily fed. In Louisiana trials 100 lbs. of chopped sweet potatoes equalled 250 lbs. of corn or sorghum silage.[30]

In a Tennessee test with fattening cattle 100 lbs. of chopped sweet potatoes had a somewhat greater value than 150 lbs. of silage, and in a Georgia test with fattening lambs 300 lbs. of sweet potatoes fully replaced 100 lbs. of corn grain.[31]

Sweet potatoes have been used most extensively for feeding swine, pigs often being turned in the field to harvest the crop. When pigs are grazed on sweet potatoes or are fed the harvested tubers, the best results are secured if they are fed one-third to one-half

the usual grain allowance, in addition to protein and mineral supplements. Only well-grown pigs or older hogs should be grazed on the crop, as sweet potatoes are too bulky for small pigs. Sweet potatoes produce hard pork, but pigs heavily fed on them tend to be paunchy and have a low dressing percentage.

In Louisiana tests it required 4.3 lbs. of sweet potatoes to equal 1 lb. of grain and other concentrates, when fed in dry lot; and 4.9 lbs. of the potatoes (but not including the vines eaten) to equal 1 lb. of corn when the crop was hogged-down.[32] The value was much lower when proper supplements were not provided.

Since sweet potatoes supply about one-third as much total digestible nutrients as corn, these values are somewhat lower than would be expected from the chemical composition. In a South Carolina test cooked sweet potatoes, fed with an efficient protein supplement, produced just as good gains on fattening pigs as did corn with the same supplement.[33] On the other hand, much less satisfactory results were secured from raw sweet potatoes.

Cooked sweet potatoes were used satisfactorily in a ration for laying hens in a Louisiana trial.[34]

Satisfactory silage was made in a trench silo from chopped sweet potatoes, without preservative, in a Georgia experiment.[35]

640. Sweet potato vines.—The green weight of the sweet potato vines per acre from a good crop of sweet potatoes is greater than the usual yield of corn forage, and the vines are a nutritious forage. Sometimes stock are turned on sweet potato fields to graze on the vines after the crop is harvested. However, often but little use is made of the vines because it has been necessary to harvest them by hand, since they are rooted in the soil every few inches of their length. Machines have been developed to solve this harvesting difficulty.

Sweet potato vines are hard to cure into good hay, as they are very high in water, but they make satisfactory silage without a preservative. Allowing the vines to wilt before ensiling them is probably advisable. In an Alabama test sweet-potato-vine silage was equal to corn silage for fattening cattle, and in North Carolina trials silage made from a combination of sweet potato vines and cull sweet potatoes was equal to corn silage for dairy cows.[36]

641. Mangels; fodder beets.—Mangels, or mangel wurzels (*Beta vulgaris*, var.), are very low in dry matter, having only 9.2 per cent. Yet due to the heavy yields—20 to 30 tons per acre on good soil and under favorable conditions—they produce a large amount of dry matter per acre. Because they stand well out of the ground, mangels are much more easily harvested than sugar beets, and they also keep better in winter storage than sugar beets, rutabagas, or turnips. They likewise stand drouth and hot weather better than rutabagas or turnips. Mangels should not be fed until after they have been stored for a few weeks, as the freshly-harvested roots may cause scouring. Half-sugar mangels, which are crosses between sugar beets and mangels, are richer in dry matter and sugar than are mangels.

Mangels are a very satisfactory feed for dairy cows, beef cattle, or sheep, except that they should not be fed to rams or wethers for long periods, because of possible danger from urinary calculi. (632) In New York tests 700 lbs. of mangels equalled 100 lbs. of dried beet pulp in feeding value for dairy cows.[37] For dairy cows, mangels and sugar beets have an advantage over rutabagas and turnips, because there is no danger of tainting the milk.

Fodder beets are considerably higher in dry matter than are mangels, and therefore have a higher value per pound. In English trials 100 lbs. of fodder beets equalled 190 lbs. of mangels for dairy cows.[38] Cows tended to go off feed if fed more than 60 lbs. of fodder beets daily.

642. Sugar beets.—The sugar beet (*Beta vulgaris*, var.) has been so developed for sugar production that some strains now contain 16 per cent or more of cane sugar. The yields are smaller than those of mangels, but owing to the higher sugar content sugar beets generally produce about as much dry matter per acre. However, they require more labor in harvesting than mangels, as they set deep in the ground. They are well liked by stock and are sometimes fed to dairy cows on test. As in the case of mangels, it is not wise to feed sugar beets to rams or wethers for long periods. (632)

The composition and value of beet pulp and beet molasses are discussed in Chapter XXIII.

643. Beet tops.—In harvesting sugar beets for sugar production, the crowns are cut off, because they contain salts which interfere with the recovery of sugar from the juice. When gathered without undue waste, the tops, which include the crowns and the leaves, will weigh from 45 to 75 per cent as much per acre as the marketed beets. Often the tops are purchased, not on the basis of

the weight of the tops, but at a certain price for the tops from each ton of marketed beets.

To utilize the tops, various methods are used: Cattle or sheep may be grazed on the tops in the field. The tops may be put into small piles, allowed to cure out more or less, and then hauled to the feeding yards. Sometimes the tops are ensiled, and occasionally they are dehydrated. Pasturing the tops may be the most economical method of using the tops, if the weather is dry enough to avoid considerable wastage, but does not usually give the maximum feeding value per acre.

Beet tops are decidedly laxative and should therefore be fed in moderation. The silage is less laxative than the fresh tops, but it is best not to feed more than 8 to 30 lbs. per head daily to cattle, depending on their size, or more than 3 lbs. to sheep. Beet leaves contain considerable oxalic acid, which is poisonous if animals receive too large amounts. It is best to feed 2 ounces of finely-ground limestone or chalk with each 100 lbs. of tops, as calcium changes the oxalic acid to insoluble calcium oxalate. Adding the calcium supplement reduces trouble from scouring. The oxalic acid is decreased somewhat in field curing.[39] If there is considerable dirt adhering to the tops, as much as possible should be removed before feeding the tops or ensiling them. Otherwise digestive disturbances may result.

The tops may be fed in larger amounts to cattle and sheep, in proportion to their live weight, than to horses or swine. This is because the fermentations in the paunch of ruminants destroy some of the oxalic acid.

Beet tops are generally ensiled in trench silos or in stacks above ground. The tops should be as green as possible.[40] They need not be run through a silage cutter and need no tramping, as they settle well with their own weight. It is a good plan to allow a period of 2 to 3 days between ensiling each layer of 3 to 4 feet of green tops. Ensiling the tops alone is preferable to the methods sometimes used of ensiling them in alternate layers with straw or in combination with dry fodder or stover.

Beet tops and beet-top silage give the best results when fed with legume or other hay and along with grain, instead of being used as the only roughage. When thus fed as part of a balanced ration, they are satisfactory for fattening cattle, sheep, and lambs, and for dairy cattle. In 15 Nebraska experiments with fattening lambs the beet tops from each ton of sugar beets saved, on the average, 24 lbs. concentrates plus 102 lbs. alfalfa hay, and slightly more rapid gains were secured when beet tops were added to the ration of grain and alfalfa hay.[41]

In Nebraska experiments when beet top silage was fed as the only roughage to fattening lambs, serious death losses of wether lambs occurred from urinary calculi.[42] (252) If alfalfa hay was also fed and the lambs actually ate 0.50 to 0.75 lb. of alfalfa a day, the losses were greatly reduced. Feeding soybean oil meal as the protein supplement also decreased the losses.

The value of beet tops and beet-top silage per ton will vary widely, as there is a large range in the percentage of dry matter contained. In Idaho and Nebraska experiments with fattening lambs a ton of beet-top silage, fed with alfalfa hay, equalled 333 lbs. alfalfa hay plus 85 lbs. grain or other concentrates in feeding value.[43] Beet tops, cured more or less, or beet-top silage has had an even higher relative value for dairy cows, fattening cattle, or fattening lambs in other experiments.[44] On the other hand, in a North Dakota experiment when fattening steers were fed too large an allowance of beet-top silage, they scoured badly and the silage was worth only one-quarter as much as corn silage.[45] On the average, beet-top silage will probably be worth approximately one-half as much per ton as corn silage. If dairy cows are fed moderate amounts of beet-top silage after milking, the flavor of the milk is not affected markedly.[46]

In a New York trial 5 per cent of dehydrated sugar beet leaves was satisfactory as a substitute for alfalfa meal in a ration for chicks.[47] A larger amount depressed growth, unless the percentage of calcium in the ration was increased, to make the oxalic acid insoluble.

644. Rutabagas.—The rutabaga, or swede (*Brassica napobrassica*), which is grown extensively in Great Britain and Canada, ranks next to the mangel in ease of cultivation. Sheep prefer it to all other roots. Rutabagas and turnips do not require such fertile soil as mangels, but do best where the climate is cool. In the central part of the corn belt and southward much of the growing season is too hot for them and they are apt to grow large necks, instead of developing good-sized roots. Like other turnips, rutabagas are apt to taint the milk of cows, unless fed only immediately after milking.

645. Turnips.—Turnips (*Brassica rapa*) are more watery than rutabagas and do not keep so well. Hybrid turnips, crosses between the turnip and the rutabaga, keep better than ordinary turnips. Maturing early,

large yields of turnips are often secured without cultivation. Though used mainly for sheep, they can also be fed to cattle.

646. Carrots.—Carrots (*Daucus carota*) usually yield much less than the root crops previously discussed; they are more particular in their soil and climate requirements; and the cost of growing the crop is higher. They are therefore of little importance for stock feeding. Occasionally, carrots are grown for horses, which are very fond of these roots. Yellow carrots can be used as a source of carotene in poultry feeding.

In Ohio tests carrots were ensiled with corn forage, at the rate of 1 ton of carrots and tops to 2.25 tons of corn, to make a silage especially high in carotene.[48] When fed to dairy cows, this maintained a high vitamin A value and a yellower color in winter milk.

647. Parsnips.—The parsnip (*Pastinaca sativa*) is the favorite root crop with dairymen on the islands of Jersey and Guernsey. Parsnips contain about as much dry matter as sugar beets, but as the yield in this country is relatively low and the roots are difficult to harvest, they are rarely grown here for stock feeding.

648. Jerusalem artichoke.—The tubers of this hardy perennial (*Helianthus tuberosus*) are sometimes grown for human food, for industrial uses, or for feeding livestock. They resemble the potato in composition, except that the chief carbohydrate is inulin, instead of starch. Though artichokes have often been recommended enthusiastically for livestock, they have proved less economical or useful than our common crops and have never been used to any appreciable extent for stock feeding in this country.[49] In various tests the yield of tubers has usually ranged from 6 to 15 tons per acre.

The forage may be cut and used for silage or as a green soiling crop, yielding 5 to 9 tons per acre, but the yield of tubers is greatly reduced by cutting the tops for forage. Artichoke silage does not compare favorably in value with corn silage.

The tubers are difficult to harvest and do not keep well in storage. They live over winter in the ground, and, even when dug in the fall, enough are usually left to make the next crop. Because of this, they may sometimes become a weed. Pigs may be turned in to harvest the tubers, but should be fed grain in addition, as they will make but little gain on artichokes alone. For swine feeding, artichokes are less valuable than corn grown for hogging down, or than other forage crops.

649. Chufa.—The chufa sedge (*Cyperus esculentus*), frequently a weed in damp fields on southern farms, produces small, chaffy tubers that remain in the ground uninjured over winter. In certain sections of the South chufas are often used for fattening swine, which are turned in to harvest the crop.[50]

Chufas grow best on sandy soils, yielding 36 bushels of 44 lbs. each per acre in Florida tests. As they are very low in protein, they should be supplemented by protein-rich feeds. Good crops of chufas have made 296 to 613 lbs. of pork per acre, after making allowance for the other feed consumed by the pigs. However, they produce a soft carcass which can be hardened only by prolonged feeding of hardening feeds.

650. Cassava.—Cassava (*Manihot utilissima*), a bushy tropical plant with fleshy roots like sweet potatoes, can be grown in Florida and along the Gulf Coast. Cassava is used for the manufacture of tapioca starch or for feeding cattle or swine. The growing of cassava in this country has declined, because other crops give larger yields at less expense.

From 5 to 6 tons of roots, containing 25 to 30 per cent of starch, are produced per acre. Some varieties contain much prussic acid and must be heated or dried before feeding, to drive off this poison. The varieties grown in this country are not poisonous. In Hawaiian tests the results were satisfactory when cassava roots supplied not over one-third the dry matter in rations for pigs, but a greater proportion for pigs or dairy cows caused scours.[51]

The value of *dried cassava meal*, or manihot meal, the by-product from cassava starch factories, is discussed in Chapter XXIII.

II. Miscellaneous Succulent Feeds

651. Rape.—Dwarf Essex rape (*Brassica napus*), one of the cabbage family, is often grown in the northern and central part of the United States as a temporary pasture crop or as a soiling crop. Rape provides excellent forage over a long season; it is easily grown and requires no cultivation; it thrives on any fertile soil adapted to corn; and the seed is cheap. Rape pasturage has a high nutritive value, for the leafy portions are nearly as rich as alfalfa in protein, on the dry matter basis. Since the young

plants are not injured by light frosts, rape may be seeded in early spring and should be 8 to 10 inches high and ready for grazing 7 or 8 weeks later. If not pastured too heavily, the crop will provide forage until late in the fall, for the plants are not killed by ordinary frosts. Rape should never be grazed so closely that only the bare stalks remain, or the new growth will be greatly reduced. Rape is not satisfactory for silage.

Although rape commonly produces the best yield when sown early in the spring, it will make a satisfactory crop when seeded as late as June or early in July, if sufficient moisture is available. For fall feeding, rape may be sown in corn previous to the last cultivation, and it is sometimes seeded in spring grain. In the South rape is an excellent winter forage crop for fertile soils.

Rape is used chiefly as a pasture crop for swine and sheep. It is also satisfactory for cattle, but dairy cows should be fed rape or grazed on the crop only immediately after milking, to avoid tainting the milk. Access to clover or bluegrass pasture when on rape is advantageous for cattle and sheep, as it reduces the danger from bloat. Sometimes stock must be accustomed to rape, but later they become fond of it. Animals on rape should have plenty of salt, as this checks any undue laxative effect.

Rape Excels as an Annual Forage Crop in the North

At small expense rape furnishes excellent pasturage from early summer to late fall.

Rape requires a rich soil and does best in a moist, cool season. In Ontario, Canada, an average of 19 tons of rape forage per acre was secured in tests over 15 years.[52] Under unsuitable conditions rape does not do well and also is often seriously damaged by plant lice.

In the northernmost states rape is often seeded for pasture in combination with oats and peas, or with only oats or barley. The combination furnishes even earlier feed than rape, and if conditions are favorable, the rape comes on after the other forage is grazed off, and lasts until late fall. In Wisconsin tests oats-peas-and-rape pasture or oats-and-rape had a little higher value for pigs than rape alone, but farther south, or in other sections where field peas do not thrive so well, rape is superior to such a mixture.[53]

Rape is more widely grown in this

country for sheep pasture than any other annual crop. It is used chiefly as a supplement to permanent pastures when they become scanty in midsummer and later. Rape or mixtures including rape were decidedly superior to bluegrass pasture for lambs in Ohio and Wisconsin tests, but in Kentucky excellent bluegrass pasture was nearly equal to rape or rape mixtures.[54]

As rape may cause bloat in sheep, the same precautions should be taken as with alfalfa. (**49**) A combination of oats and rape is less apt to cause bloat than rape alone. Allowing lambs to graze on rape when it is wet or too immature may cause scours. It is best to keep sheep, especially lambs, off a field of rape drenched with dew or rain until the leaves are dry. Often shepherds cut rape and feed it as a green soiling crop, instead of pasturing it. This is safer but takes considerable labor. Rape may be pastured late in the fall, even after it freezes, though there may then be more danger of bloat.

Rape or a combination including rape is the best annual pasture crop for swine where rape thrives. Experiments have shown clearly that such pasture is nearly equal to alfalfa or red clover in value per acre. (**466, 472**) Where alfalfa thrives, it slightly excels rape, chiefly because it need not be reseeded each year and also because it is a legume and thus builds up the soil. Though the portion of rape plants eaten by pigs is nearly as rich as alfalfa in protein, pigs self-fed, free choice, corn and a protein supplement generally eat a somewhat greater amount of supplement on rape than if on alfalfa or clover.

Rape occasionally causes blistering or sunscalding of swine, especially of white ones. This may occur when pigs graze in rape when it is wet and then get into hot sunshine. Care should be taken to rub crude oil, vaseline, or lard on any blistered spots. As very little trouble is generally experienced, even with white pigs, one should not hesitate to use rape for swine pasture.

A large-growing variety of rape, called "giant rape," or "broad-leaved rape," is often grown in Great Britain but is not common in the United States. In New York tests this variety furnished slightly more grazing for sheep than Dwarf Essex rape.[55]

Rape is sometimes fed as a green feed to poultry, or rape may be used for poultry pasture. Rape produces very dark colored egg yolks.

652. Cabbage.—On rich ground cabbage (*Brassica oleracea*) produces as much palatable forage as do root crops, but because more labor is required in its cultivation, it is grown but little for stock feeding. Cabbage is prized by shepherds when preparing stock for show, and is also used for feeding poultry and milk cows. Like other plants of the mustard family, it should be fed after milking, to avoid tainting the milk. When cabbage is raised for market, the small heads and the leaves may be fed to stock, unless the leaves carry too much poisonous spray residue.

653. Kohlrabi.—Another member of the cabbage family, kohlrabi (*Brassica caulorapa*), can be grown wherever rutabagas thrive. Under favorable conditions for rutabagas, kohlrabi yields less, but in hot weather it does better than rutabagas. Since the thickened, turnip-like stems stand well above the ground, the crop is readily pastured by sheep, which also relish the leaves. Kohlrabi apparently does not taint the milk when fed to dairy cows.

654. Kale; marrow-stem kale.—Kale (*Brassica oleracea*, var. *acephala*), a cabbage-like plant that does not form heads, is grown extensively for stock feeding in this country only in the northern Pacific-Coast district. A large-growing variety, "thousand-headed kale," is there considered the best fall and winter soiling crop for dairy cows and is also used for sheep and swine. In that district kale will usually remain green most of the winter.

In Oregon tests 131 lbs. of kale equalled 100 lbs. of corn silage for dairy cows, and the yield of kale was so much higher than that of corn that an acre of kale was worth 2 acres of corn silage.[56] Kale, like others of the mustard family, should be fed after milking to avoid tainting the milk.

Marrow-stem kale, a kind with enlarged, fleshy stems, is used to some extent in Great Britain as a soiling crop, especially for sheep. It is also sometimes ensiled, being chopped and preferably mixed with straw or hay, as it is very low in dry matter.[57]

655. Sunflowers as a forage crop.—Where the season is too short and cool for corn, sunflowers (*Helianthus annuus*) are sometimes used for silage and as a green soiling crop. Sunflowers are not affected so much as corn by cool weather or injured by light frosts, and therefore produce a good crop where corn would fail. Sunflowers should be ensiled when one-half to two-thirds of the heads are in bloom. If cut later the forage is less palatable, and the heavy heads make the forage difficult to handle, as it is top-heavy.

Sunflowers are inferior to corn for silage where the latter thrives, even though they will often yield more forage per acre. This is because the silage is decidedly less palatable and is much lower in feeding value. Average sunflower silage has only 12.2 per cent of total digestible nutrients, compared with 18.3 per cent for well-matured corn silage. For dairy cows [58] and for beef cattle [59] good sunflower silage has usually been worth much less per ton than corn silage or sorghum silage. Its value has been more similar to oat-and-pea silage or oat-vetch-and-pea silage. The value of sunflower silage has been especially low per ton in comparison with that of well-matured corn silage, in tests where pigs have followed the cattle to utilize the unchewed corn kernels in the manure. For sheep sunflower silage has also generally been much inferior in value per ton to good corn or sorghum silage, or even to that from peas and oats or peas and barley.[60]

When stock are accustomed to good corn silage, it is sometimes difficult to get them to take sunflower silage, but they can usually be induced to eat it, if it is mixed with more palatable feed. Sunflower silage is sometimes rather constipating and had best be fed with laxative feeds, such as legume hay.

Sunflowers are sometimes grown in combination with corn for silage in cool regions, with the hope of securing a larger yield or a surer crop than from corn alone, and obtaining a more palatable silage than from sunflowers alone. If this is done, it is best to plant the corn and the sunflowers in alternate rows, because otherwise the tall-growing sunflowers will tend to choke out the corn.

Considering the rather low palatability and feeding value of sunflower silage, it would generally seem advisable to use a hay crop for silage in regions too cool for corn, instead of growing sunflowers for this purpose.

656. Pumpkins, squashes, and melons.—The pumpkin (*Cucurbita pepo*) is sometimes planted in cornfields and the fruits used as a relish for horses, cattle, and pigs. Pumpkins contain only 10.4 per cent dry matter and their feeding value per ton is therefore low. One ton of pumpkins, including seeds, is about equal in feeding value for dairy cows to 333 to 400 lbs. mixed hay or 800 lbs. corn silage.[61]

Pumpkins are not satisfactory as the only feed for pigs, but they may be fed along with grain and a protein supplement. It will take 10 tons or more of pumpkins to equal 1 ton of grain in feeding value for pigs.[62] Cooking pumpkins for swine is not beneficial. There is a common opinion that pumpkin seeds are harmful to stock, but this is not true.[63] Feeding the seeds alone, however, is apt to cause indigestion on account of the high fat content.

In Colorado hogs have been fattened exclusively on raw *squashes* (*Cucurbita*, spp.). The meat had a good flavor, but the fat had an undesirable yellow color.[64]

Melons, especially pie melons, or citrons, are occasionally fed to stock.[65]

657. Honeysuckle.—In some areas of the southeastern states semi-evergreen honeysuckle vine (*Lonicera*, spp.) grows rampantly over shrubs and up trees in wooded pastures, furnishing some forage for stock. In Georgia tests the young growth, which is the part eaten by stock, was about equal to good grass hay in content of digestible nutrients, on the dry-matter basis, and produced fair gains on young cattle as the only feed.[66]

658. Hydrolyzed sawdust; fodder cellulose.—By heating sawdust with dilute acid under pressure, a portion of the woody fiber can be converted into more digestible compounds, including certain sugars. Cattle will not usually eat the hydrolyzed sawdust unless mixed with well-liked feeds. However, dairy cows have been successfully fed concentrate mixtures containing one-quarter to one-third of the hydrolyzed sawdust. When thus used the feeding value of hydrolyzed sawdust made from either pine or fir has differed greatly in the limited tests made with it.[67] The value has ranged from only one-fourteenth as much as grain to about one-half as much as grain. Because of the expense of producing the hydrolyzed sawdust, the method would be of practical importance only during a prolonged period of serious feed shortage.

"Fodder cellulose" has also been prepared for stock feeding by treating sawdust by a sulfite process, similar to the process used in making paper pulp, which removes the indigestible lignin and leaves mostly

wood cellulose. In the feed shortage in Europe during the recent war, fodder cellulose or paper pulp, gave satisfactory results when fed to ruminants as a partial substitute for other feed. Since it is tasteless, it was usually moistened with molasses to improve the palatability.[68] Using fodder cellulose as the only roughage, or with only straw, for a long time, produced digestive trouble, due to the suppression of the bacterial digestion in the rumen. (45)

659. Mint hay or silage.—Hay or silage can be made from green peppermint (*Mentha piperita*) after the oil is extracted by steam distillation. In a Michigan test mint hay was a satisfactory substitute for alfalfa hay for dairy cows.[69]

660. Pineapple tops.—Chopped pineapple tops, or crowns, which form about 7 per cent of the weight of the fresh fruit (*Ananas comosus*) were palatable and equal to green Napier grass as the only roughage for dairy cows or dairy heifers in Hawaiian experiments.[70] The cows ate 60 lbs. or more of the tops per head daily. Chopped pineapple tops, with molasses as a preservative, made satisfactory silage, but there was an excessive loss by seepage, because of the low dry matter content.

661. Ramie meal.—Ramie meal is a new dehydrated product made from the leaves and tops of ramie (*Boehmeria nivea*), a plant that is grown for fiber in certain sections of Florida and other regions with a climate that is warm enough. It resembles alfalfa meal in protein, carotene, and fiber content. Ramie meal has been satisfactory as a substitute for alfalfa meal for poultry, and may be fed to cattle, mixed with well-liked concentrates.[71]

662. Spurry.—Spurry (*Spergula sativa*), which requires a cool, moist growing season, is sometimes used as a catch crop for feeding green to stock on sandy land in northern Europe. It has proved of little value in this country, not being adapted to our hot summers.

663. Tree leaves and twigs.—The leaves and small branches of trees are sometimes fed to farm animals in certain countries when better feed is scarce. In some of the mountain range areas of this country the leaves and twigs of shrubs form no small part of the forage eaten by stock.

Tree leaves are more digestible than twigs, and the better kinds compare favorably with ordinary hay in feeding value. Leaves of the ash, birch, linden, and elder are valued in the order given. They are eaten with relish, especially by goats and sheep. These statements apply only to leaves gathered at the right stage and cured like hay. Leaves which turn brown and drop from the trees in autumn are worthless for feeding farm animals. Brush feed, consisting of ground and crushed twigs, stems, and leaves, has occasionally been used in certain mixed feeds as an absorbent for molasses.

664. Vegetable wastes.—Vegetable tops, leaves, and other wastes, which are a by-product in preparing such vegetables as carrots, broccoli, turnips, etc., for the table or for dehydration or canning, can be utilized for stock feeding. Dehydrated vegetable wastes of this kind can be used as substitutes for alfalfa meal in poultry feeding, as they are very rich in carotene.[72]

Sometimes dried vegetable wastes are solvent-extracted to produce carotene or other plant-pigment concentrates. The residue of course has no vitamin A value but may be used to replace part of the protein supplement for poultry or cattle.[73]

Cooked potato peelings can be used in swine feeding in the same manner as cooked potatoes, but have a somewhat lower value per pound.[74]

III. Plants of the Arid Districts

665. Sagebrush, saltbush, and the greasewoods.—Many species of sagebrush (*Artemisia*, spp.), saltbush (*Atriplex*, spp.), and greasewood (*Sarcobatus*, spp.) flourish in the arid portions of the West where drouth, alkali, and common salt make conditions unfavorable for most of the ordinary forage crops. On many ranges they furnish much of the feed consumed by stock.[75] The Australian saltbush, introduced into certain sections of the West, has proved of much less value than was first expected. It is less drouth resistant than the native saltbushes and is rather unpalatable on account of its high salt content.[76]

666. Yucca and sotol.—It has been found that various species of yucca (*Yucca*, spp.), including soapweed and the Spanish bayonet, and also sotol (*Dasylirion*, spp.), a near relative of the yuccas, furnish valuable emergency feed for range cattle in the Southwest. Usually the dry leaves are first burned off and then the plants are cut with an axe and hauled to a central location. Here they are finely chopped or shredded by special machines and fed to the cattle. The prepared forage may also be ensiled. The compact heads of sotol are used similarly. Cattle may be maintained on either of these emer-

gency feeds alone through long drouths, when they would otherwise starve.[77]

667. Russian thistle.—The Russian thistle (*Salsola kali*, var. *tragus*), now growing over great areas of the western plains, is used to some extent for pasture, hay, or silage when better feeds are scanty on account of drouth.[78] The mature plants are woody, spiny, loaded with alkali, and very unpalatable. For hay Russian thistles should be cut when in bloom, before the spines harden and the plants become woody. If the plants are too mature when made into hay, the hay should be sprinkled with water several hours before feeding, to soften the spines. Even early-cut Russian thistle hay is best fed in chopped form as only part of the roughage. If stock will not eat it satisfactorily, sprinkling it with diluted molasses will help.

Silage made from Russian thistles may be very unpalatable unless molasses is added as a preservative, or unless thistles that are rather immature and low in dry matter are wilted before ensiling them.

668. Kochia, or burning bush.—Kochia (*Kochia scoparia*), also called burning bush, fireball, fireweed, or summer cypress, is a large coarse annual that is sometimes grown as an ornamental, because of its fiery autumnal color. It has become established as a weed in some districts. South Dakota tests indicate that when kochia is cut before flowering it makes satisfactory, leafy hay, which supplies nearly as much total digestible nutrients as alfalfa.[79] Kochia makes satisfactory pasture for cattle, though not equal to alfalfa.[80]

669. Cacti.—During periods of drouth the cacti, especially prickly pears (*Opuntia*, spp.), are a boon to stockmen on the southwestern ranges.[81] Because of their peculiar structure and habits, cacti can survive long drouths, though they make little growth at such times. The prickly pear cacti, which grow wild on the ranges, may be fed where they stand by first singeing off the spines with a gasoline torch, or they may be gathered and run through machines which chop them in such a manner that the spines are comparatively harmless. Cacti grow slowly on the range, and can usually be harvested but once in 5 years, even under favorable conditions.

SINGEING PRICKLY PEAR WITH A GASOLINE TORCH

After the spines have been singed off, cattle can feed on prickly pear without harm. Another method is to cut the cacti and run them through machines which chop them, rendering the spines comparatively harmless. (From U.S. Department of Agriculture.)

Prickly pear cacti contain about 16.6 per cent dry matter, being less watery than roots, and cane cacti (*Cholla*, spp.) contain somewhat more dry matter. Since they are low in protein, all the cacti should be fed with a protein-rich concentrate or roughage. Cacti alone will not maintain stock. Though desert cattle sometimes subsist on them for three months of the year, they become very

emaciated. Fed in large amounts with no dry feed, cacti tend to produce scours.

Spineless cacti, long known but sometimes exploited as a novelty, have only limited usefulness for stock feeding, because on the open range cattle will graze and destroy them and also because they must be enclosed in rabbit-proof fences, for rabbits are fond of them.[82] Spineless cacti will not stand the winters in the northern states.

The chief importance of cacti is to furnish emergency forage for stock in the semi-arid regions in case of drouth, for these plants are able to utilize most efficiently small and irregular supplies of moisture. For this purpose plantations of the spiny cacti may be established on the open range, where they will be able to grow and hold their own until drawn upon in time of serious drouth, for cattle will not graze them when other feed is reasonably abundant.

IV. Poisonous Plants and Poisonous Feeds

In this volume only the briefest mention can be made of some of the most important facts concerning poisonous plants and poisonous feeds. One in trouble should consult a competent veterinarian or his state agricultural college or experiment station.

670. Prussic acid, or hydrocyanic acid poisoning.—Under certain conditions some plants cause the death of stock from prussic acid, or hydrocyanic acid poisoning. Of the several species of plants which may cause such poisoning the most important are the sorghums, Johnson grass, chokecherry, black cherry, arrow grass, velvet grass, Christmas-berry, and Sudan grass.

When the plants are poisonous, the poison is usually not present in appreciable amounts as free prussic acid, but in the form of complex compounds, called glucosides. These must be broken down and the free prussic acid liberated before poisoning occurs. However, the glucosides are readily broken down by an enzyme usually present in the plant. The poison may be set free in the digestive tract of an animal eating the dangerous plants, and it may also be set free in the plants on wilting or being bruised. Cattle and sheep are affected by the poison, but horses and swine are apparently not injured, or only very rarely.

The poisonous property usually develops in dangerous amounts only when the growth of the plants is checked or stopped by drouth, frost, trampling, mowing, or wilting. Freezing that ruptures the plant cells causes a rapid liberation of free prussic acid.[83] Young plants generally contain much more of the poison than when growth is well advanced. Certain seeds, such as vetch seed, may sometimes contain dangerous amounts of the glucosides.

Prussic acid poisoning by the sorghums occurs chiefly in the western plains states, which are especially subject to drouth. Only a few cases have been reported in the humid sections of the South. When sorghum or other forage is thoroughly cured as hay or dry fodder, the poisonous property is usually greatly reduced. Silage that has been stored for several months is generally safe. Sudan grass is much less apt to cause poisoning than the sorghums, and is therefore much safer to use for pasture or for a soiling crop.

Stock affected by the poison often die in a few minutes after eating only a small amount of the dangerous forage, perhaps only a few mouthfuls. Therefore, there is usually no time for treatment. In pasturing sorghums the only safe way is to turn an animal of little value into the field first. If no poisonous effects are observed, the rest of the stock may then be allowed to graze the crop.

Glucose in the rumen checks the rate of formation of the prussic acid, and it has been found that it is wise to give cattle or sheep a starchy feed, such as corn or the grain sorghums, before allowing them to graze on or in the vicinity of plants that may be dangerous. The starch in the grain forms glucose in the digestive tract and thus aids in preventing trouble.

If a poisoned animal is discovered in time, a drench of molasses diluted with water may be helpful, but a veterinarian should be called at once to give additional treatment.

671. Ergot.—The seeds of rye and of certain grasses, especially Dallis grass and Argentine Bahia grass, are sometimes attacked by the ergot fungus, which changes the seed into enlarged black masses. This ergotized seed is poisonous to stock if consumed in appreciable amounts. Injury to stock on pasture of Dallis grass or other grass affected by ergot can be prevented by not allowing the grass to go to seed.

Rye grain containing ergot may injure animals continuously fed it. The poor results often secured when rye grain forms a large part of the ration for pigs may be due in part to ergot in the grain. In a Montana experiment when brood sows were fed grain containing not over 1 per cent of ergot during pregnancy, many of their pigs were so weak that they died soon after birth, and the sows

showed almost complete lack of udder development.[84]

Animals showing any symptoms of injury from ergot should have their feed changed and should be warmly housed and liberally supplied with nourishing feed.

672. Scabbed grain.—Sometimes barley and other small grain is seriously affected by the fungus which causes scabbed kernels. Scabbed grain does not injure cattle, sheep, or poultry.[85] On the other hand, horses refuse grain that is very scabby. Pigs also will not eat much badly scabbed grain and are made sick if more than about 10 per cent of the ration consists of scabbed barley kernels.

673. Smut on corn and other grain.—Corn forage or corn ears affected by smut are apparently harmless to stock, though animals may possibly be injured if fed large amounts of smut separated from such corn.[86] There is no need of removing the masses of smut from corn forage as it is being fed or ensiled or of removing smut from dry fodder. Grain sorghum smuts are also not injurious to stock,[87] and wheat damaged by stinking smut did not injure poultry in a Maryland test.[88]

674. Spoiled or moldy feed; forage poisoning; botulism.—Many cases have been reported in which the death of stock, especially of horses, has apparently been caused by the eating of spoiled feed. From time to time serious losses of horses and cattle have occurred, particularly in the Mississippi Valley, from so-called "forage poisoning," or "corn-stalk disease." Such trouble occurs most frequently in stock grazing on cornstalk fields or fed spoiled corn forage or corn silage. Investigations have not yet revealed the exact cause of such trouble, though it is apparently caused by the spoiled feed. In turning stock on stalk fields, especially when the crop was not well ripened, it is a good plan to put one or two of the least valuable animals in first, and watch results closely.

Most of the common molds are not at all poisonous, and therefore feed which is badly molded may be entirely harmless. On the other hand, certain molds are dangerous, and the presence of mold may indicate that other changes may have taken place which may produce poisons, as in the case of damaged sweet clover hay or silage. Horses are most susceptible to injury from spoiled feed, and sheep are also affected more often than cattle. Great care should therefore be taken not to feed spoiled silage or other feed to these two classes of stock. Hay which is slightly moldy (except sweet clover hay) is not ordinarily dangerous, though it tends to cause trouble from heaves in horses. Sweetclover disease, caused by damaged sweetclover forage, has been discussed previously. (480)

Cattle are rarely affected by feed that is slightly moldy or spoiled, and usually they may be fed silage with traces of mold without danger. Any large masses of spoiled silage should be discarded, and should be placed where horses or sheep cannot eat it. Swine are not usually affected by moderately moldy feed, though they are injured by scabbed barley, as has been pointed out previously in this chapter. However, sometimes moldy corn may kill pigs. For example, the death of 25 out of 100 pigs on a North Dakota farm was apparently caused by a particular kind of mold.[89]

Occasionally, livestock are poisoned by botulism, because of the toxin produced in certain materials by the anaerobic botulinus organism. Horses, mules, and poultry are more susceptible to the poisoning than other stock. While the dangerous feed is often spoiled or moldy, in some cases it is unfortunately normal in appearance.[90] Botulism has occurred in animals on pasture which have been forced to drink stagnant water, doubtless due to the water having passed through spoiled vegetation. Decayed carcasses of animals or bones are apt to be dangerous. Suspected samples of feed should never be tasted by persons, as mere traces of the poison may prove fatal.

In case of suspected botulism or other forage poisoning, the feed should be changed and a competent veterinarian consulted. The use of antitoxin is beneficial in cases that are not too far advanced.

675. Various poisonous plants.—A considerable list of plants are definitely poisonous to stock, and particularly on the western ranges serious losses of stock sometimes occur from poisoning.[91] Some plants are dangerous only at certain stages of growth, and some affect one class of animals but not others.

Stock seldom eat poisonous plants by choice, but only when induced or compelled to do so by the scarcity of other feed.[92] When the grazing is scanty, the animals should therefore be kept away from spots definitely known to be infested with such plants. In moving herds or flocks on the range, special precautions should be taken when it is necessary to pass over a trail that has been used by many other animals, for all good feed will have been consumed, and the stock will eat whatever is left.

Among the plants that may cause serious trouble on the western ranges are larkspurs, loco weeds, lupines (from the time the pods appear), death camas, bitterweed, greasewood (early in spring), certain milkweeds, water hemlock (tubers and young shoots), woody aster, halogeton, and some vetches.

Most of these plants are poisonous because of toxic alkaloids they contain. Halogeton is poisonous because it has on the dry basis as much as 20 per cent of soluble oxalates (salts of oxalic acid). In the body these oxalates form insoluble calcium oxalate, thus using up the supply of calcium in the tissues. The animal dies as a result of extreme calcium deficiency.

Hungry animals are most susceptible to halogeton poisoning, because they eat more halogeton, even though it is not palatable. Also, if there is considerable other food in the rumen, some of the soluble oxalates will be destroyed in the rumen fermentations or converted there into insoluble calcium oxalate.[93] When animals must be trailed through an area heavily infested with halogeton, they can be protected to a large degree by feeding once a day pellets containing a high amount of calcium supplement.[94] Halogeton is usually more dangerous in the fall than in late winter, when the soluble oxalates have been leached out to some extent.

Other important plants which may cause poisoning are the common brake fern or bracken, mountain and sheep laurel, certain nightshades, cocklebur (young plants before the leaves are developed, and also the seeds), corn cockle, horse tail rush, potato tops, and the foliage of tung trees. It is of interest that bracken and also horse tail rush are poisonous because they contain an enzyme which destroys the vitamin thiamine in the food. White snakeroot and rayless goldenrod not only cause a poisoning of stock, called "trembles," but also the milk produced by affected animals may cause the same poisoning in humans or suckling animals.

Mustard seed and rape seed contain glucosides that may produce poisonous volatile oils when the seed is eaten. These seeds may therefore be dangerous, and also mustard-seed or rape-seed oil cake from which the dangerous property has not been removed. Castor beans and castor-bean oil meal are very dangerous to stock.

676. Selenium poisoning.—It has been found that certain shale soils in areas of considerable size in some of the western states contain appreciable amounts of selenium, a mineral which is poisonous to animals. Some plants, including woody aster, certain vetches, and Nuttall's saltbush, accumulate the selenium in their tissues, and are poisonous only when growing on these soils. When these plants die and decay, other plants, even the grasses or cultivated crops, may take up the selenium and become toxic. The poisoning known as "alkali disease" and "blind staggers" in certain northern range areas is due largely to this cause.

A very small amount of certain arsenic compounds in the feed or water largely or entirely counteracts the injurious effects of selenium in such forage.[95] Excellent results have been secured when 25 parts of arsenic, in the form of sodium arsenite, have been added per million parts of the salt supplied to the stock on ranges where trouble from selenium poisoning has previously occurred. (1.9 grams of sodium arsenite per 100 lbs. of salt supplies this amount. The arsenite must be mixed with the salt with extreme care, as it is itself poisonous.) Certain arsonic acid compounds (arsanilic acid and 3-nitro-4-hydroxyphenylarsonic acid), which are less toxic than sodium arsenite, were effective in counteracting selenium toxicity in recent South Dakota experiments with pigs.[96] The feeding of protein supplements and a plentiful supply of vitamin A seem to help to prevent selenium poisoning.[97]

677. Nitrate poisoning.—In semi-arid regions and during drouth in other areas, nitrate occasionally accumulates in small grain forage and other plants in poisonous quantities.[98] (584) Plants injured by 2,4-D or other weed killers may have dangerous amounts of nitrate.

Most of the cases of nitrate poisoning reported have been caused by oat hay or oat straw, but rarely forage from wheat, barley, sorghum, corn, or weeds may have a dangerous amount of nitrate. Cattle are much more apt to be affected than are sheep or horses. The occurrence of a dangerous quantity of nitrate in forage can be detected only by chemical analysis. Therefore certain of the western experiment stations make, for a small charge, nitrate determinations in forage samples sent in by farmers.

The nitrate in the forage is changed to nitrite in the digestive tract. When this is absorbed into the blood, it changes the hemoglobin into a form that cannot transport oxygen and the animal is asphyxiated.

678. Other poisoning of farm animals.—Many cases of livestock poisoning occur through animals having access to poisonous

substances, such as spray materials, paint, or fertilizer, which have been carelessly left around. Such losses can be avoided by great care on the part of every person handling these materials. All lead paint is poisonous. Animals will not only lick newly painted surfaces or discarded paint containers, but may even lick enough lead paint off an old fence or building to be poisoned.

Animals will not usually eat enough common salt to be injured at all, but if a strong brine is left where they have access to it, they may drink enough to be harmed.

When forage crops are sprayed or dusted with the proper amount of a recommended insecticide or fungicide, the hay, silage, or pasture forage does not contain enough of the spray material to injure livestock. The animals should be removed from a pasture while it is being treated.

In the case of dairy cows fed forage that has been treated with certain insecticides, including DDT, chlordane, toxaphene, and dieldrin, the insecticide may pass into the milk in sufficient amounts to be detectable.[99] If fattening animals are fed such forage up to the time of slaughter, the meat may have a detectable amount of the insecticide.[100] Methoxychlor, aldrin, or heptachlor could not be detected in the milk of cows fed forage treated with a proper amount of the insecticide.[101]

Seed grain that has been treated with mercurial or certain other fungicides should not be fed to stock.

It has been found recently that X-disease, or hyperkeratosis, a serious disease which has sometimes occurred in cattle, is caused by highly chlorinated naphthalenes in certain lubricants and other petroleum products.[102] Because of their excellent lubricating quality under pressure, these compounds have been added to some greases and oils for lubricating machinery. They also occur in certain wood preservatives and asphalt products.

X-disease affects chiefly cattle, and sheep are much less susceptible to injury. The disease, which may be fatal, causes great thickening of the skin, which becomes hard, dry, and wrinkled. It also produces lesions in the mouth and on other mucous membranes, diarrhea, and other symptoms. Part of the toxic effect of these compounds seems to be an anti-vitamin A action, in interfering with the conversion of carotene into vitamin A.

Because of the danger from X-disease, cattle should be kept away from all products that might be dangerous, such as used crank case oil and old oil drums. Drainage from grease racks or farm machinery sheds should not be allowed to contaminate exercise lots or pastures.

QUESTIONS

1. Why are roots unimportant for stock feeding in the United States? Under what special conditions may the use of roots for feeding be advisable in this country?
2. Discuss the composition and feeding value of roots.
3. Compare the economy of roots and corn silage for stock feeding.
4. What have experiments shown concerning the value of roots for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) swine; (e) poultry?
5. Discuss the value and use for stock feeding of any of the following that may be of importance in your district: (a) Potatoes; (b) sweet potatoes; (c) sweet potato vines; (d) mangels; (e) sugar beets; (f) sugar beet tops; (g) rutabagas; (h) turnips; (i) carrots; (j) parsnips; (k) artichokes; (l) chufas; (m) cassava.
6. State the characteristics of rape and discuss its use in stock feeding.
7. Are any of the following fed to stock in your region? If so, how is the forage used: (a) Cabbage; (b) kohlrabi; (c) kale; (d) sunflowers; (e) pumpkins, squash, or melons; (f) vegetable wastes.
8. If the following are of importance in your section, tell how they may be used in stock feeding: (a) Sagebrush, saltbush, and the greasewoods; (b) yucca and sotol; (c) Russian thistle; (d) cacti.
9. Tell the main facts concerning the following: (a) Prussic acid poisoning of stock; (b) ergot; (c) scabbed grain; (d) smut on grain; (e) spoiled or moldy feed; (f) botulism.
10. What general precautions should be taken to avoid injury to stock from poisonous plants?
11. Does selenium poisoning or nitrate poisoning occur in your region?

CHAPTER XX

CORN AND OAT GRAINS AND THEIR BY-PRODUCTS

I. THE CHARACTERISTICS OF THE CEREALS AS STOCK FEEDS

679. Importance of the cereal grains in stock feeding.—In the previous chapters emphasis has been placed on the importance for livestock of good roughage, including pasture, hay, dry fodder, and silage. However, for efficient livestock production, concentrates are usually needed in addition to good roughage. This is because forage alone is too low in digestible nutrients and net energy to meet the needs of stock for high production.

To secure the greatest profit from good dairy cows, it is generally necessary to feed them a liberal amount of concentrates in addition to plenty of high-quality roughage. Likewise, in order to produce the quality of meat desired by consumers, fattening cattle and lambs must usually receive considerable quantities of grain or other concentrates. Horses or mules cannot do much work on roughage alone. Swine and poultry must be fed chiefly on concentrates, because their digestive systems can make only limited use of forage.

The cereal grains and their by-products form by far the greater part of all the concentrates used for livestock in this country. Indeed, all classes of stock except poultry are frequently fed only farm-raised grain and roughage with the small amounts of protein or mineral supplements in addition that may be needed to balance their rations. The grains and by-products therefore merit first consideration among all the concentrates.

680. Nutritive characteristics of the grains.—The cereal grains are all high in starch and either low or relatively low in fiber. They are therefore rich in total digestible nutrients and net energy. In addition, nearly all the grains are highly palatable to stock, which is important with animals being fed for production. Rye is the only one of the common grains that is sometimes not well liked by stock.

Corn, wheat, and the grain sorghums lead in amount of total digestible nutrients and net energy, being closely followed by barley and rye. Oats, with their thick hulls, are higher in fiber and therefore lower in digestible nutrients.

Corn and rice are decidedly low in protein, and other grains are relatively low in protein. The proteins of the grains are also of poor quality, for they contain only small amounts of certain of the essential amino acids. (120) In feeding swine and poultry, efficient results cannot therefore be secured unless protein supplements of good quality are fed in addition to grain, so that sufficient amounts of these amino acids will be supplied.

It is fortunate indeed that for dairy cows, beef cattle, sheep and horses, legume hay will fully make good any deficiencies of the cereal grains in quality of protein and will also largely or even entirely balance the ration in amount of protein. (126) Even for swine, legume hay and especially legume pasture help to make good the deficiencies of the cereal grains in amount or quality of protein. (124)

The grains are not rich in phosphorus, but are slightly higher in this mineral nutrient than are the common hay crops, including both the legumes and grasses. (148) Corn and the grain sorghums are lower in phosphorus than oats, wheat, barley, or rye. Certain of the grain by-products, especially wheat bran and wheat middlings, are rich in phosphorus. On the other hand, corn gluten meal and brewers' grains do not contain much more phosphorus than the grains themselves.

All the grains are very low in cal-

cium, and this fact must be borne in mind in livestock feeding. (**146**) Corn is especially deficient in this respect.

None of the grains contains an appreciable amount of vitamin D. (**204**) With the exception of yellow corn, none of the grains supplies any significant amount of vitamin A value. (**197**) The grains are fairly rich in thiamine but are low in riboflavin. Wheat, barley, and the grain sorghums contain considerable niacin, but corn, oats, and rye are much lower in content of this vitamin. All the grains supply vitamin E in fair amounts.

CORN IS BY FAR OUR MOST IMPORTANT CROP

In acreage and in value Indian corn is the most important crop in the United States.

II. INDIAN CORN AND ITS BY-PRODUCTS

681. Importance of Indian corn for grain.—Indian corn (*Zea mays*), or maize, is by far the most important crop in the United States. Nearly one-quarter of our entire crop acreage each year grows corn, and of the entire crop, over 85 per cent is harvested for grain. Corn holds this position in our country because it surpasses all the other cereals in yield of both grain and forage, wherever it thrives.

Previous to the restrictions on corn acreage in the United States, about 90,000,000 acres of corn were grown annually for all purposes. During recent years the acreage has been reduced to about 80,000,000 acres. However, because of the general use of high-yielding hybrid corn and more adequate fertilization, the total production of corn grain has not been lessened.

For the 5-year period, 1949–1954, the average yield of corn grain in this country was 37.7 bushels per acre, a record high average yield, in comparison with 25.2 bushels for the 10-year period of 1924–1933. The high yield per acre during recent years was brought about by the general adoption of high-yielding hybrids, combined with improved fertilization and a succession of years of favorable weather.

The general requirements for the growth of corn and its use and value as a forage crop have already been discussed in Chapter XVII.

682. Composition and nutritive value of corn.—Corn grain is one of the best feeds for all classes of stock, when it is so fed as to take advantage of its great merits and to correct its deficiencies. It ranks far ahead of any of the other cereals in importance for livestock feeding in the United States, about 90 per cent of our huge corn crop being fed

to farm animals. The value and use of corn for each class of stock are discussed later in this chapter.

Corn ranks high among the grains in total digestible nutrients and net energy. The high content of total digestible nutrients (81.9 per cent for dent corn of No. 1 grade) is due to the following: Corn is very rich in nitrogen-free extract, which is nearly all starch; it is higher in fat than any of the other cereals except oats; and it is very low in fiber and therefore highly digestible. Another advantage of corn is that it is probably the most palatable of the cereals for most farm stock. A possible explanation for this is the high fat content, and the fact that on chewing, the kernels break into nutty particles which are more palatable than meal from wheat, for example.

The statement is sometimes made that corn is too "heating" to be fed to fattening animals as the only or the chief grain in warm weather. It is true that more care may be necessary to prevent such stock from going off feed in hot weather when fed all the corn they will eat. This is because corn is such a concentrated feed. However, even in hot weather, corn gives excellent results when fed as the only grain to fattening animals, if care is taken not to overfeed them.

Since it is so rich in starch, corn is naturally low in protein. Also, the protein of corn is of poor quality for nonruminants, because it is low in two of the essential amino acids—tryptophan and lysine.

Most of the varieties of hybrid dent corn now so widely grown in this country are apparently lower in protein than the varieties formerly raised. In the compilation of analyses published by the author in 1936, the average protein content of No. 2 dent corn was 9.4 per cent.[1] The figures for the average composition of dent corn given in Appendix Table I of this volume are based on nation-wide studies made during two seasons by the Committee on Feed Composition of the National Research Council of the composition of the leading hybrid varieties in the various states.[2]

In the first year, which was a good corn year, the average protein content of Grade No. 2 dent corn over the country was only 8.7 per cent. The following year, which was a year in which some corn did not mature so well, the average protein content on the same dry-matter basis (85 per cent dry matter) was a trifle higher, being 8.9 per cent.

This decrease in the protein content of our corn grain since the general adoption of hybrid varieties seems to be due to a combination of factors. Because of the high yield of hybrid corn, together with the heavier planting rates now commonly used, the available nitrogen supply in the soil is nearly exhausted before the corn matures, unless the crop is fertilized unusually liberally with nitrogen. Consequently, the protein content of the grain is reduced.[3] In addition, even when well fertilized with nitrogen, most of the hybrid varieties apparently tend to produce grain of somewhat lower protein content than did the old open-pollinated varieties formerly grown.[4]

Corn is extremely low in calcium, having but 0.02 per cent. This means that there is only 0.4 lb. of calcium in an entire ton of the grain. Corn also has less phosphorus than other common grains, No. 2 dent corn having an average of only 0.26 to 0.27 per cent.

It is pointed out in following paragraphs that yellow corn has considerable vitamin A value, while white corn has none. Both yellow and white corn lack vitamin D. Corn is fairly rich in thiamine, but it is lower than wheat or barley in niacin, and, like all the other grains, is low in riboflavin.

683. High-protein or high-fat corn. —Through long-continued inbreeding, plant breeders some years ago developed strains of corn in which the grain was much higher than normal in protein or in fat. However, the yield of these inbred strains was too low for them to be of practical importance. By utilizing high-protein inbred strains in the breeding of certain hybrid varieties, hybrids have been produced which are high in protein but also yield fairly well.

High-protein hybrids have been de-

veloped commercially that produce grain having 11 to 15 per cent protein when the crop is liberally fertilized with nitrogen. However, the yield of the present high-protein hybrids is generally so much lower than that of the best ordinary hybrids that their use has not become common.

Experiments have shown that in high-protein corn the chief increase is generally in zein, which lacks lysine and has very little tryptophan.[5] (117) The total protein of such corn is therefore lower than usual in these two essential amino acids. Consequently, in feeding high-protein corn to swine or poultry, this lack must be corrected by the use of protein supplements, such as fish meal, soybean oil meal, or blood meal, which have good supplies of these amino acids.[6]

The use for cattle or sheep of high-protein corn grain or silage made from such corn reduces the amount of protein supplement needed to balance the ration. However, this saving is not usually sufficient to offset the lower yield of the high-protein corn.[7]

684. Yellow corn has vitamin A value.—It has been shown in Chapter VII that yellow varieties of corn and varieties with yellow endosperm (the starchy part of the kernel) have considerable vitamin A value, because of the content of carotene and related pigments. (197) Yellow corn is therefore an important source of vitamin A in stock feeding. However, it has much less vitamin A value than green forage or even well-cured hay. Part of the yellow color in yellow corn is due to xanthophyll, which has no vitamin A value. White corn or other corn with white endosperm has practically no vitamin A value.

In general, deep yellow corn has a higher vitamin A value than light yellow varieties, although the vitamin value is not always proportional to the depth of yellow color. This is because the proportion of xanthophyll varies. On storage for 2 or more years, the vitamin A value of yellow corn sometimes decreases considerably, without any great change in color of the corn. (195)

The vitamin A value of red varieties or varieties with hulls of other colors will depend entirely on whether the endosperm is yellow or white. The gluten of yellow corn is richer than the rest of the kernel in vitamin value. Therefore corn gluten feed and corn gluten meal from yellow corn are richer than yellow corn in vitamin A value.

Whether or not yellow corn will have a higher value than white corn for stock feeding, will depend on whether the other feeds in the ration provide plenty of vitamin A value. In general, white corn is equal to yellow corn for all stock on green, actively-growing pasture and also for dairy cattle, beef cattle, sheep, or horses which are fed a reasonable amount of good-quality hay or silage.[8] For swine or poultry that are not on pasture, the difference in vitamin A value of yellow and white corn may make all the difference between profit and failure, unless care is taken to provide sufficient of the vitamin in other feeds.

For example, in 5 Wisconsin tests young pigs not on pasture were fed to market weights on either white corn or yellow corn, supplemented by tankage, skimmilk, or whey and linseed meal (all of which supply little or no vitamin A).[9] The pigs fed yellow corn made decidedly more rapid and economical gains than those fed white corn, and on white corn many pigs became runts or died because of the vitamin deficiency. On the other hand, for pigs on good pasture there was no difference in the value of the two kinds of corn, because green forage supplies an abundance of vitamin A value. Adding a small amount of leafy, well-cured legume hay to the ration entirely corrects the deficiency of vitamin A in white corn and in the small grains.

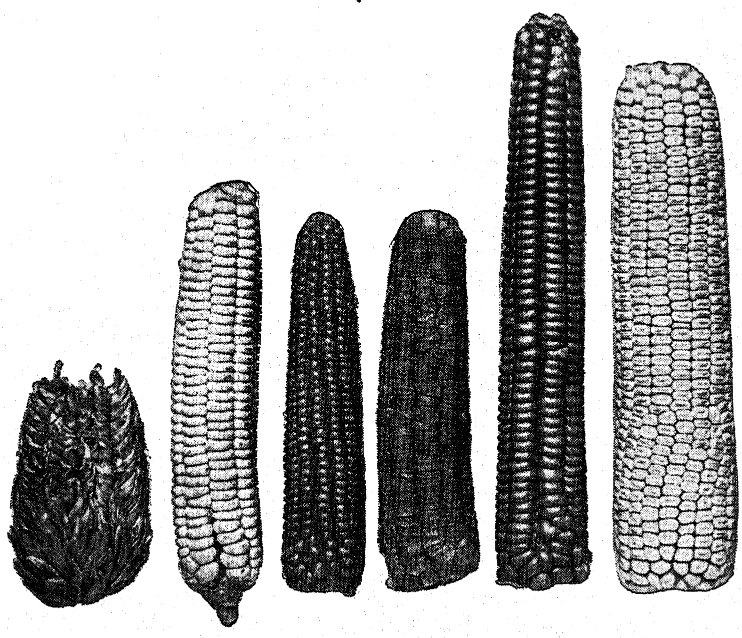
Yellow corn produces yellow color in the yolks of eggs and in the shanks, beak, and skin of fowls, while white corn does not. This is due partly to the carotene it contains, but chiefly to the xanthophyll. (14) Except for this difference, white corn is equal to yellow for poultry, if the ration otherwise supplies plenty of the vitamin.[10]

Previous to the discovery in 1920

that yellow corn has vitamin A value, only about one-half of the corn sold under Federal inspection on the large markets in this country was yellow. By 1942, 90 per cent of the corn on these markets was yellow. Because of the scarcity of white corn, it commanded a premium in price, as it is required for certain special uses, such as the manufacture of corn flakes.

is changed to tough, horny starch as they mature. Mature sweet corn has somewhat more protein, much more fat, and correspondingly less carbohydrates than dent corn.

Pop corn that is off-grade and unsuitable for popping may be used for feeding. It should be ground as the kernels are very hard. Pop corn is higher than dent corn in protein and fat.



EARS OF DIFFERENT TYPES OF CORN

From left to right: Pod corn, a primitive type; soft corn, an unimproved type having no horny starch; pop corn; sweet corn; flint corn; dent corn. (From Wisconsin Station.)

685. Types of corn.—*Dent corn* is the type generally raised in this country. *Flint corn* has about the same chemical composition and feeding value as dent corn, but the kernels are harder because the starchy portions are mostly horn-like and flinty. Since flint corn is harder, there may be more advantage in grinding it than in the case of dent corn. In 3 Ohio experiments shelled flint corn was worth 3 per cent less than dent corn when self fed to fattening pigs.[11]

Sweet corn is rarely fed to stock. Before hardening, the milky kernels of sweet corn have much glucose, which

Waxy corn, in which the starch is waxy and similar to tapioca starch, is grown to a limited extent because of the special qualities of the starch for food and technical uses. Though waxy corn was less palatable to pigs in Nebraska trials, it was fully equal to ordinary corn in feeding value.[12] It also equalled dent corn in value for chicks.[13]

686. Hybrid corn; hardness of kernels.—The kernels of some of the hybrid corn varieties are considerably harder than those of the old open-polinated varieties, and also most of the hybrids are lower in protein. Several experiments

have therefore been conducted to compare various hybrids with open-pollinated varieties which were formerly grown widely.[14] In some of the tests the hybrids have been fully equal to the older varieties for swine or for fattening cattle, but in other tests they have been worth slightly less per bushel. For example, in 7 Ohio experiments with growing and fattening pigs fed plenty of protein supplement, hybrid corn was worth 97 per cent as much, on the average, as open-pollinated varieties. Any such small difference in feeding value is much more than offset by the higher yield of hybrid corn adapted to the particular section.

If the hybrid corn is low in protein, obviously, a greater amount of protein supplement must be fed with it to balance the ration.

687. Storage of corn.—For safe storage in the fall in the usual types of corn cribs, ear corn should be sufficiently matured so that the kernels do not contain more than about 20 per cent of water. The cobs will then have a considerably higher percentage of water. Shelled corn stored in an ordinary bin may spoil in warm weather if it has more than 13 to 14 per cent of water. In cool weather it can be shipped without much risk of heating when it contains as much as 16 to 18 per cent of water, but such corn cannot be stored safely for any long period.

For satisfactory storage, ground corn must be thoroughly dry, containing not more than 12 to 13 per cent water, or else it is apt to mold or turn rancid. Even then it may gradually become sour; therefore corn should not be ground a long time before it is fed.

In the North corn is stored on the farm mostly as husked ear corn, but in the South the husks are left on, in order to protect the ears from weevils.

688. Grades of shelled corn; weight of corn.—Shelled corn is sold on the large markets according to the Federal corn grades. These are based on the percentage of water and also on the percentage of unsound kernels and foreign material. Since the feeding value depends, first of all, on the water content, separate averages are given in Appendix Table I for corn of the various grades.

According to the Federal grades, the percentage of water in corn must not exceed 14 per cent for Number 1; 15.5 per cent for Number 2; 17.5 per cent for Number 3; 20.0 per cent for Number 4; and 23.0 per cent for Number 5. Corn containing more than 23 per cent water, or which does not come up to the standards in other respects, must be sold as "Sample grade."

Seventy pounds of dry dent ear corn of good varieties yield 1 bushel, or 56 lbs., of shelled corn, but in early fall buyers frequently demand 75 to 80 lbs. or more, according to the estimated water content. Flint varieties have a somewhat smaller shelling percentage than dent corn.

689. Soft corn.—When corn is frosted before the grain matures, the ears contain too much water for ordinary storage. Such soft corn can best be utilized for stock feeding. The entire crop may be ensiled; it may be put in small, well-built shocks in the field until it is fed; or silage may be made from the snapped ear corn. Soft corn should be used up during the cold weather, as it will spoil when the weather becomes warm. Soft corn can be dried with heated air, for storage.

Soft corn that has not reached the dent stage is lower in nitrogen-free extract and fat than mature corn, and is therefore lower in energy value. However, it is higher in protein.

Soft corn, if not moldy, may be fed to all classes of stock.[15] It is well to accustom animals to it gradually, to avoid possible digestive disturbances. Experiments have shown that when soft corn is of good quality, the feeding value of the dry matter in it is about equal to that in mature corn. Of course, the value per acre is much lower, because of the reduced yield of dry matter from the immature crop. The gains of fattening cattle may be somewhat slower on soft corn than on mature corn, owing to a smaller consumption of dry matter.

Moldy soft corn had best be fed to cattle or swine, as it may be dangerous to horses and even to sheep, though sheep sometimes do well on it. When soft corn becomes moldy, it is worth considerably less, on the dry basis, than sound corn.

Snapped ear corn makes satisfactory silage, which may be fed as a substitute for other forms of corn grain to cattle or sheep.[16] It has not given good results in tests with pigs. The snapped corn must be chopped finely by running it through a silage cutter and should be tramped well in the silo. If the corn is past the milk stage, it is well to add approximately 40 gallons of water to each ton of ears. Chopped straw or corn stover, well wet down, should be used to cover the ear corn at the top of the silo, to prevent the waste of the more valuable feed. Flood-damaged ear corn may be similarly ensiled.

690. Forms in which corn is fed.—Corn grain is fed in the following different forms: ear corn, snapped corn, shelled corn, cracked corn, ground corn, corn-and-cob meal (ground ear corn), and ground snapped corn. Sometimes hogs or fattening lambs or cattle are turned into a ripe field of standing corn to harvest the crop. The relative values of the various ways of feeding corn to the different farm animals are discussed in articles which follow. The best form for any class of stock will depend primarily on how thoroughly the animals chew the grain when fed whole.

Ground corn is the term commonly used in this book for the entire ground grain from which the hulls or germs have not been removed. Ground corn is also called *corn chop* or *corn meal.* Very coarsely ground corn is called *cracked corn.*

When corn is ground for stock, medium-fine grinding is preferable to fine grinding, for such ground corn is more palatable, and also much less power and labor are required for the grinding. As has been mentioned previously, ground corn in any form does not keep so well in storage as shelled corn or ear corn.

Especially for poultry feeds, the fine siftings are often removed from cracked corn or coarsely-ground corn, and the product is then called *screened cracked corn, screened ground corn* or *screened corn chop.*

The fine siftings that are removed, with or without the light fragments of of the hulls, etc., are known as *corn feed meal.* This has about the same composition and value as ground corn, except it is slightly higher in protein and fat, but it is also somewhat higher in fiber.

Corn-and-cob meal, ground ear corn, and *ear corn chops* all mean the entire ground ear corn, including the cobs. The cobs usually form about 20 per cent of the weight of corn-and-cob meal. Because of the ground cobs, corn-and-cob meal is more bulky than ground corn.

On account of the rubbery nature of corn cobs, more power is needed to grind ear corn than shelled corn. However, it may cost less to grind the ears than to shell the corn and then grind it.

When the entire corn ears in the husks, or shucks, are ground, the product is called *ground snapped corn,* or *ear corn chops with husks.*

The use of corn-and-cob meal and ground snapped corn for the various classes of stock is discussed in the following articles.

691. Corn cobs.—Except when ear corn was ground into corn-and-cob meal, but little use was made of ground corn cobs for stock feeding until recently. Because of the great quantity of cobs available annually in this country, many experiments have been conducted during the past few years to find how ground corn cobs can be utilized for feeding ruminants.

Corn cobs have 32 per cent fiber and even for ruminants usually supply only 45.9 per cent of total digestible nutrients, which is a trifle more than in oat straw or cottonseed hulls. They have only 2.3 per cent of protein, and this is digested so poorly that they furnish no digestible protein. They are also very low in minerals, having but 0.04 per cent phosphorus. They do not supply carotene and are very low in other vitamins.

The experiments have shown that to enable ruminants to utilize ground corn cobs, the ration must be amply supplemented, or else the nutrients will not be provided to permit efficient digestion of the ground cobs by the rumen bacteria.[17] (45) The supplements needed are: (1) A plentiful supply of protein. This can be replaced partly by a protein

substitute, such as urea. (2) A source of readily available energy, such as molasses or ground grain. (3) Additional phosphorus and other minerals. (4) Unidentified factors needed by the rumen bacteria, which are furnished by high-quality roughage or by molasses.

Even when adequately supplemented, ground cobs are distinctly a roughage, and a low-grade roughage at that. However, ground cobs may be an economical roughage when available for not much more than the cost of hauling and grinding. They cannot replace corn grain or other feeds high in total digestible nutrients and net energy.

Most of the experiments to study the use of ground cobs have been with beef cattle, and cobs apparently have the most usefulness for them, especially as part of the ration for wintering young stock or beef cows. Data are limited concerning the value of ground cobs for dairy cows or sheep.

Swine or poultry can get little nourishment from corn cobs. Ground cobs should therefore not be added to their rations, except as ear corn is ground for swine to form corn-and-cob meal. (**703**)

Corn cobs must be ground fine enough so larger particles will not be refused. In grinding them with a hammer mill, a one-half or five-eighths inch screen should be used. As ground cobs are not palatable when fed separately, the supplement should be well mixed with them.

When ground cobs are high in moisture, considerable heating and molding will occur if they are stored longer than about 2 days in warm weather.

692. Ground corn cobs for beef cattle.—Experiments have shown that when properly supplemented, ground cobs can be used as the only roughage for wintering young beef cattle or beef cows. In Indiana trials calves have gained 1.0 to 1.5 lbs. a day when wintered on ground corn cobs and 3.5 lbs. per head daily of such a protein-rich supplement as Purdue Supplement A, described in Chapter XXVIII.[18] In these experiments ground cobs, fed as the only roughage, produced greater gains than did oat straw or cottonseed hulls, but not nearly such large gains as did corn silage similarly supplemented.

In Kansas trials calves made as good gains with properly supplemented ground cobs for the only roughage as with prairie hay.[19] However, more protein supplement was of course needed with the ground cobs. In Nebraska tests ground cobs satisfactorily replaced half the corn silage in well-balanced rations for wintering calves.[20]

Ground cobs, fed with 4.8 lbs. per head daily of a protein-rich supplemental mixture, were as satisfactory as grass hay for wintering beef cows in North Carolina trials.[21]

Ground corn cobs can be used to replace part of the corn grain in a ration for fattening cattle. The use of corn-and-cob meal, which contains about 20 per cent of cobs is discussed later. (**696**) When corn is high in price or the supply is limited, it may be economical to include more ground cobs in the concentrate mixture, especially in fattening cattle of the lower grades that are not carried to a high degree of fatness.

When twice as much ground cobs as are present in corn-and-cob meal have been included in rations for full-fed fattening cattle, the gains have usually been less rapid than when corn grain, without cobs, was used instead.[22] Also, the cattle do not reach as high a finish and bring a slightly lower price on a discriminating market. If pigs follow the fattening cattle, less pork is produced on high-corn-cob rations. Considering these factors and also the greater amount of protein supplement needed with added ground cobs, they have been worth about one-half as much per ton as corn grain when thus used.

In an Iowa experiment fattening cattle made excellent gains when self-fed only a mixture of corn-and-cob meal, ground cobs, soybean oil meal, cane molasses, urea, minerals, stilbestrol, and vitamin A supplement.[23]

693. Ground corn cobs for dairy cattle and sheep.—Indiana and Virginia experiments show that ground cobs are very unsatisfactory as the only rough-

age for dairy cows, even when well supplemented, but that the milk production is only slightly decreased when ground cobs are substituted for half of the hay usually fed.[24] In another Virginia trial the milk production was only slightly decreased when 20 per cent of ground cobs was added to a concentrate mixture that contained one-half corn-and-cob meal.[25]

A mixture of ground cobs, soybean oil meal, bone meal, trace minerals, and vitamin A-D supplement satisfactorily replaced bromegrass hay for dairy heifers in an Illinois trial, but the hay was cheaper.[26] In Kentucky experiments ground cobs, well supplemented, were equal to cottonseed hulls as the roughage for dairy heifers.[27]

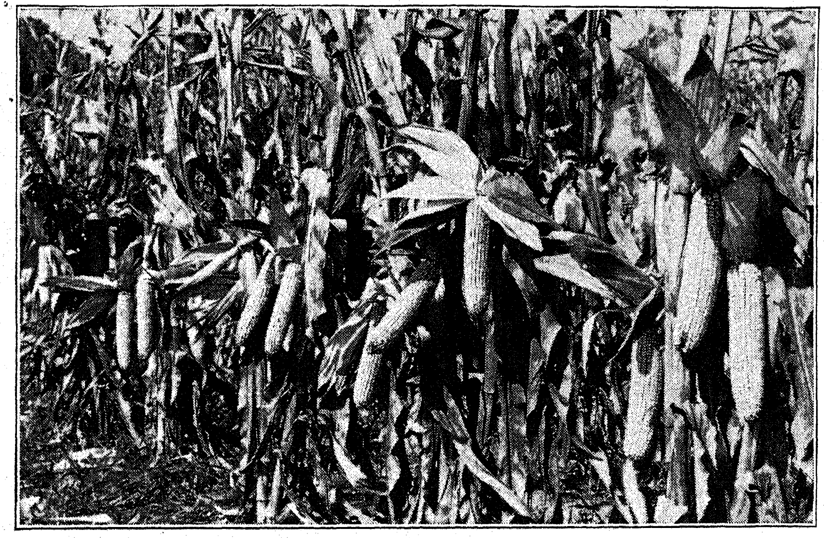
Ground corn cobs had no appreciable value as part of the ration for wintering breeding ewes in 3 Ohio experiments, and in an Indiana trial less satisfactory results were secured with ground cobs, properly supplemented, as the only roughage than with corn silage or grass silage.[28]

694. Corn for dairy cattle.—Corn is an excellent feed for dairy cows or other dairy cattle, when fed with feeds that make good its deficiencies. Since corn is a heavy feed, most dairymen prefer to use it as only part of the concentrate mixture, mixing ground corn with such bulkier feeds as wheat bran or ground oats. Nevertheless, for cows of average production, a mixture consisting only of ground corn and protein supplement can be used satisfactorily. (**1016**, **1071**)

A West Virginia test shows that, contrary to the beliefs of some, a concentrate mixture consisting chiefly of corn does not increase the trouble from mastitis in dairy cows.[29]

Good legume hay, especially alfalfa, makes good the deficiency of corn in protein. Therefore, for average cows such a mixture as one-half ground corn and one-half ground oats, without protein supplement, is satisfactory, if half the roughage, on the dry basis, is alfalfa.

On the other hand, the results are very unsatisfactory when corn or such a mixture as corn and oats is fed without a protein supplement to cows receiving little or no legume roughage. For example, in an Illinois experiment one group of cows was fed on corn grain as the only concentrate, with timothy hay,



A FINE FIELD OF DENT CORN

The husks have been stripped back to show the ears.

corn silage, and a small amount of clover hay for roughage.[30] Another group was fed a well-balanced ration of clover hay, corn silage, and a mixture of ground corn and gluten feed. The cows fed the balanced ration produced 47 per cent more milk and 39 per cent more fat than those fed the same weight of concentrates and roughages in the unbalanced ration.

Experiments have proved conclusively that it pays to grind shelled corn or ear corn for dairy cows.[31] If cows are fed whole shelled corn, as much as 18 to 35 per cent of the grain passes through the digestive tract unchewed and with but little digestion of the nutrients in these whole kernels. The corn should be ground to only a medium degree of fineness, for extremely fine grinding is unnecessary and unduly expensive. Merely cracking it is not sufficient to ensure thorough digestion.[32]

Shelled corn is chewed thoroughly by calves up to 8 or 9 months of age and therefore it is unnecessary to grind it for them.[33] Heifers also chew corn much more thoroughly than do cows. In Michigan experiments only 6 per cent of the shelled corn was not masticated by calves and 11 per cent by heifers, in comparison with 23 per cent by cows.[34]

When other bulky concentrates are not included in the ration, 100 lbs. of corn-and-cob meal, including the cobs, may equal or approach in value an equal weight of ground corn. On the other hand, if the concentrate mixture is already reasonably bulky, corn-and-cob meal is apparently worth no more than the amount of corn grain it actually contains, fed as ground corn.[35] If the cost of grinding ear corn to corn-and-cob meal is less than the cost of shelling it and then grinding the shelled corn, it is economical to use corn-and-cob meal, even if there are other bulky feeds in the concentrate mixture.

In 3 Ohio trials simple concentrate mixtures were compared, which consisted only of either corn-and-cob meal or ground shelled corn supplemented by soybean oil meal and minerals.[36] In each of the tests the milk production was a trifle less on the corn-and-cob meal mixture, but the average difference was less than 2 per cent. Corn-and-cob meal was the more economical form for feeding, because of the lower cost of preparation.

695. Corn for beef cattle.—Corn is by far the most important concentrate for fattening cattle in the United States. It excels not only because of its richness in total digestible nutrients, but also because no other grain is so palatable to cattle. It is therefore taken as the standard with which other grains are compared.

Corn is likewise very satisfactory for breeding cattle, if it is properly fed. Breeding stock should not be fed so much corn that they become too fat. Also, care must be taken to provide plenty of protein and minerals, and some legume hay should be included in the ration, if available.

When beef cattle are on good pasture or when they are fed roughage of good quality furnishing sufficient vitamin A value, there will be no difference in the value of yellow corn and white corn for them. (684)

Whether to feed fattening cattle all the corn or other grain they will eat or to limit the amount of grain, is a problem of the utmost importance. This is discussed in Chapter XXVIII.

696. Preparation of corn for beef cattle.—*Shelled corn* is a common form for feeding corn to fattening cattle that are followed by pigs to consume the kernels that escape chewing and digestion. Experiments have shown that in such cases there is not generally sufficient saving through grinding corn to warrant the expense.[37] On the other hand, it pays to grind shelled corn or ear corn for cattle over 8 or 9 months of age, if they are not followed by pigs.

Coarse or medium-fine grinding of corn is preferable to fine grinding, for such grain is more palatable and also less apt to cause heavily fed fattening cattle to go off feed. Ear corn should be ground fine enough so that the cattle will eat the fragments of cobs. Up to 8 or 9 months of age, calves chew corn and oats so thoroughly that it does not pay to grind these grains for them.

Cattle that are being fitted for show or sale are generally fed *ground corn*, because it usually produces a trifle more rapid gains than shelled corn or ear corn. For the same reason, it pays to grind corn when one wishes to force cattle to make maximum gains, so as to be ready for market before an expected decline in the price of fat cattle.

Some years ago *broken ear corn* was the most common form for feeding fattening cattle in the corn belt. However, with the general availability of electric power, ear corn is now generally ground into *corn-and-cob meal*, as less labor is required than in preparing broken ear corn.

If pigs do not follow fattening cattle, *corn-and-cob meal* is an economical form in which to feed corn. The daily gain is apt to be a little less than on ground corn, but the ground cobs in corn-and-cob meal save some of the other roughage. It was concluded from Ohio experiments that each 100 lbs. of corn cobs in corn-and-cob meal was worth about as much as 50 lbs. of ground corn.[38] In Indiana trials with beef calves being wintered, the gain was slightly less on corn-and-cob meal than on ground shelled corn, and 100 lbs. of corn-and-cob meal was equal in value to 90 lbs. ground corn minus 40 lbs. hay.[39]

Because of the greater bulk of corn-and-cob meal, it is easier to get cattle on a full feed of grain without digestive disturbances. Corn-and-cob meal is also a safer feed for an inexperienced feeder to use than shelled corn or ground shelled corn.

Corn-and-cob meal will even produce good gains on fattening cattle without the feeding of any other roughage than is furnished by the corn cobs present, if a special supplement is fed that makes good the deficiencies in corn cobs and corn grain that have been previously stated.[40] (691)

Formerly broken ear corn was a popular form for feeding farm-raised corn from fall until spring to fattening cattle that were followed by pigs.[41] In the summer, when the ears became dry and hard, shelled corn or ground corn gave better results. Ear corn is broken by running it through a silage cutter or other machine. It can also be sliced by means of a corn knife, or broken over the edge of the manger.

Snapped corn (ear corn with adhering husks, which has been snapped from the corn stalks) is often fed to beef cattle during fall and early winter. It is better adapted to yearlings or 2-year-olds than to calves.[42] Even for the older cattle, it had best be replaced by broken ear corn or shelled corn during the latter part of the fattening period.

Corn is sometimes fed to fattening cattle in the form of *ground snapped corn* (ear corn ground with the shucks or husks). In 6 Tennessee experiments with calves fed for baby beef, the gains were a little less rapid and the net return per steer somewhat lower on ground snapped corn than on shelled corn or ground shelled corn.[43] In 6 Georgia trials older fattening cattle gained 2.13 lbs. per head daily on ground snapped corn and 2.40 lbs. on cracked shelled corn.[44] The selling price was slightly lower for the cattle fed ground snapped corn, and 100 lbs. of ground snapped corn was about equal in value to 75 lbs. of cracked shelled corn.

697. "Cattling down" corn.—Particularly in the corn belt, fattening cattle are sometimes turned into standing corn to harvest the crop. Cattle that are at least 2 years old are much better for this purpose than younger animals. The cattle should always be brought to a full feed of grain before they are turned into the field, or they may overeat and suffer from indigestion. In using this method, it is important to feed sufficient protein supplement to balance the ration, and to have about twice as many pigs following the cattle as would be needed in dry-lot feeding. In the southern states standing, thickly-planted, mature corn is sometimes used for winter pasture for beef cows.[45]

698. Corn for sheep.—In all the corn-growing districts of this country, corn is the grain most commonly fed to fattening lambs. It is also widely used as part of the concentrates for breeding ewes and young lambs.

A ration of only corn grain and either alfalfa or clover hay is excellent

for fattening lambs, for they eat enough of the legume hay to supply sufficient protein to produce good gains. As is shown in Chapter XXX, the gains will usually be a trifle more rapid when the lambs are fed in addition a small amount of such a supplement as linseed meal or cottonseed meal. However, the addition of the supplement will generally be uneconomical.

Numerous experiments have proved that fattening lambs will not make rapid or economical gains when they are fed only corn and non-legume roughage, without a protein supplement. For example, in 7 tests lambs fed corn with timothy or prairie hay, without any supplement, gained an average of only 0.19 lb. per head daily, in comparison with 0.32 lb. for others fed corn with clover or alfalfa hay.[46] The lambs on the unbalanced ration required 46 per cent more corn and 15 per cent more hay for each 100 lbs. gain than those fed the balanced ration of corn and legume hay.

When fed in a properly-balanced ration, corn can be used successfully as the only grain for breeding ewes in winter, provided the allowance is limited so the ewes do not become too fat. However, shepherds generally prefer more bulky mixtures, such as are mentioned in Chapter XXXI.

In the corn belt, corn is extensively fed as the only grain to fattening lambs, after they are safely on feed. For fattening lambs which are hand-fed it gives excellent results when thus used, if it is properly balanced by feeds supplying plenty of good-quality protein and of calcium. When lambs are self-fed corn, some bulky feed like chopped hay or oats should be mixed with it to lessen digestive troubles, which may otherwise cause serious death losses.

Even in hand-feeding fattening lambs, it may also be safer to mix bulky feeds with corn, if they are being forced as rapidly as possible on all the grain they can be induced to eat. In these cases such a combination as 2 to 3 parts corn and 1 part oats, by weight, is excellent.

699. Feeding corn in various forms to sheep.—Corn grain is usually fed to sheep and lambs in the form of shelled corn or as ear corn. Experiments have shown clearly that there is usually no advantage in grinding shelled corn or in grinding ear corn for sheep, with the following exceptions:[47] (1) For sheep with poor teeth, (2) for young lambs up to 5 or 6 weeks of age, and (3) when fattening lambs are being self-fed such a mixture as corn grain and chopped hay, or even when they are being hand-fed all of such a mixture that they can be induced to eat.

Usually hand-fed lambs will make slightly more rapid and economical gains on shelled corn than on ground corn. Likewise, ear corn or broken ear corn has given as good or even better results than corn-and-cob meal. Corn ground coarsely is preferable to fine meal for sheep or lambs.

For fattening lambs ear corn or broken ear corn produced just as rapid gains, on the average, in 9 trials as shelled corn, when each was fed as the only grain.[48] Also, the cost of feed per 100 lbs. gain was slightly less for the lambs fed ear corn.

Sometimes fattening lambs are fed shock corn, ears and all, usually being given a small amount of shelled corn or other grain at first, until they learn to husk the corn ears.[49] The lambs may not gain quite so rapidly when fattened by this method and a little more corn may be required per 100 lbs. gain, but the method saves labor, compared with the feeding of corn in other forms.

Both ear corn and shock corn are better suited for feeding on a thick sod than in a dry lot or barn, for they may be scattered on the sod so that each lamb will have an equal chance to feed, and little will be wasted. In the lot or barn, lambs are apt to drop the ears where they become soiled, or to bunch them up in the trough so that each lamb does not get its share.

700. Fattening lambs in the corn field.—In some districts many farmers fatten western lambs in the corn field. This is called "lambing down corn." When conditions are favorable, lambs fattened in the corn field with supplemental feed make nearly as rapid

gains as those fed corn and legume hay in dry lot, but the death losses are apt to be higher.[50] In northern Colorado, such heavy death losses occurred from "overeating disease" that the practice was abandoned.

For lambing down, such supplemental crops as rape or soybeans should be grown in the corn. The lambs will usually clean up this forage long before they finish the corn. They should then be provided with good, palatable legume hay, so they will eat plenty of roughage. The best results are secured when 0.15 lb. per head daily of protein supplement is also fed from the start.

The lambs should have plenty of feed available without traveling too far, and they should have shelter from bad storms. It is the best plan to divide a large field into suitable areas by hurdles or by temporary woven-wire fencing. The lambs should be strong and healthy and should have dense fleeces which will shed water well. They should be accustomed to the corn gradually, by giving them a feed of hay in the morning the first few days before turning them on the field. At first the lambs will clean up the other vegetation in the corn field, including most of the weeds. Then they will begin eating the corn leaves and finally will learn how to husk out the corn ears and eat the grain from the cobs.

Plenty of hay and other feed should be available for feeding in bad weather or if the lambs clean up the corn field before they are fat. Severe financial losses will be incurred if one is forced to dump half-fat lambs on the market. The lambs should be inspected daily to see that all are thriving. Muddy fields are hard on their feet, as the mud cakes between their toes.

701. Corn for horses and mules.—Next to oats, corn is the grain most commonly fed to horses and mules in the United States. Several experiments have shown clearly that if work horses or mules are fed legume hay or mixed hay containing at least one-third legumes, corn is satisfactory as the only concentrate. For example, in a Missouri test mules fed shelled corn and mixed clover-and-timothy hay maintained their weights slightly better than those fed oats and hay.[51] This was in spite of the fact that each mule that was fed corn received 145 lbs. less grain and 75 lbs. less hay a year than did the mules fed oats. In this experiment there was a saving of 21 per cent of the cost of feed for the corn-fed mules.

As corn is a heavy, highly-concentrated feed, care must be taken not to feed more than is needed. It takes about 15 per cent less corn than oats to keep work horses in condition, when the ration is properly balanced in protein.

Although work horses and mules need much less protein than do dairy cows or fattening cattle or lambs, corn grain and ordinary grass hay make a ration too low in protein for the best results.[52] Therefore when corn is fed as the only grain with such roughage, a small amount of protein supplement should be added to balance the ration. This will usually save more than enough feed to be profitable, and it will also keep the animals in better condition and spirit.

If grass hay is cut reasonably early, so that it has a fair amount of protein, such a concentrate mixture as 900 lbs. of corn and 100 lbs. of oats will be satisfactory for mature work horses or mules.

Ear corn or shelled corn are the best forms of corn for feeding to horses or mules, unless their teeth are in poor condition. Grinding the grain does not make a sufficient saving of feed to justify the expense. Ear corn is preferable to shelled corn, for it keeps better, and horses eat it more slowly and chew it more thoroughly. If corn is ground for horses with poor teeth, it should be cracked or ground coarsely, for fine meal forms a mass in the stomach which is difficult to digest and may even cause colic. Corn-and-cob meal is better for horses than ground shelled corn, since it is more bulky. A slightly smaller weight of corn-and-cob meal than of oats is needed to keep work stock in condition, because oats are a little lower in total digestible nutrients.

702. Corn for swine.—Corn is the most common swine feed in the chief pork-producing districts of the United States. Indeed, it is estimated that hogs usually consume almost one-half of the total corn crop produced in this country. It is unsurpassed for growing and fattening pigs, and is therefore commonly taken as the standard with which other

grains are compared. Corn is also entirely satisfactory for brood sows and other breeding stock, when its deficiencies in protein, minerals, and vitamins are corrected, and when the amount of corn is limited so that they will not get too fat.

Excellent protein-rich pasture, such as alfalfa, clover, or rape, greatly reduces the amount of protein supplement needed to balance corn. As shown in Chapter XXXIV, it may not pay to feed any protein supplement at all to growing and fattening pigs on such pasture after they reach a weight of 100 to 125 lbs. For swine not on pasture, good-quality legume hay also helps to make good the protein deficiencies of corn. Indeed, pregnant mature brood sows can be wintered satisfactorily on nothing but corn grain, plenty of first-class legume hay, and minerals.

Experiments proved many years ago the folly of feeding corn alone or corn plus minerals to pigs not on pasture. For example, in 7 experiments with pigs averaging 69 lbs. in weight at the start, those fed corn without any protein supplement or pasture gained only half as rapidly as others fed corn and tankage, and many became stunted.[53] Each 100 lbs. of tankage fed to balance the ration saved 607 lbs. of corn. Other good protein supplements would have had a similar high value in balancing the ration.

Merely supplementing corn grain with a mineral mixture that supplies additional calcium and phosphorus, does not greatly improve the ration for pigs not on good pasture.[54] In order to produce satisfactory results, corn must be supplemented with good-quality protein, as well as with calcium and phosphorus.

Corn alone is just as unsatisfactory for pregnant sows as it is for young pigs, as is pointed out in Chapter XXXV. On the other hand, excellent results are secured with corn as the chief feed for brood sows, if the ration is properly balanced and if the allowance of corn is restricted so that the sows do not become too fat.

When white corn is used for swine feeding, care must be taken to provide plenty of vitamin A value in the other feeds in the ration.

703. Forms in which to feed corn to swine.—Corn is most commonly fed to swine in this country in the form of ear corn or as shelled corn. Numerous experiments have shown that for pigs up to the usual market weights, grinding corn does not make enough saving to warrant the expense. Ear corn usually produces as economical results as shelled corn. Sometimes pigs will make a trifle less rapid gain on ear corn than on shelled corn but will require no more actual corn grain per 100 lbs. gain.[55]

When pigs are self-fed shelled corn, they chew it even more thoroughly than when hand-fed, apparently because there is not the rush and competition among the pigs in getting their shares. In Indiana, Minnesota, and Wisconsin experiments in which pigs were grown and fattened to usual market weights on self-fed shelled corn or ground corn with good protein supplements, there was no saving whatsoever by grinding the corn.[56] The hardness of the corn did not seem to make any difference in the results of these tests, as the corn was rather hard hybrid corn in some cases.

In earlier experiments in which pigs were hand-fed, there was little or no saving through grinding corn for pigs until they reached a weight of about 150 lbs.[57] From then up to usual market weights, the saving was not usually more than 6 or 7 per cent. Soaking corn that has become very hard through storage will increase its value nearly as much as grinding it.

For feeding to brood sows, ear corn and shelled corn are the most economical forms.[58] If the sows do not chew all the kernels, they will be commonly sorted out of the droppings and thus finally utilized, for brood sows are not generally fed all the grain they will eat.

When shelled corn is ground for pigs, it should be ground to a medium degree of fineness. Pennsylvania and Wisconsin tests show that grinding to a fine meal does not increase the value of the grain over medium grinding, and the cost of labor and power is much

greater.[59] However, medium-fine grinding is preferable to merely cracking the grain.

In most of the experiments in which ear corn or shelled corn has been compared with corn-and-cob meal, the corn-and-cob meal has been less economical.[60] This is because pigs cannot digest the cobs to any appreciable extent, even when ground. If ear corn is ground for self-feeding, it must be ground fine enough to avoid clogging the self feeder.

In Georgia experiments ground snapped corn, including the husks, produced decidedly less rapid and economical gains than cracked shelled corn.[61]

704. Hogging down corn.—In some sections many farmers turn pigs into standing corn to harvest the crop. Numerous experiments have proved that this is an economical method of fattening pigs, if one does not wish to market them early, before the price drops in the fall and thus before the new corn crop is ready.[62] When corn is properly hogged down, pigs generally make fully as rapid gains as those fed corn and a good supplement in a dry lot. Also, they require no more feed per 100 lbs. gain. In addition, hogging down corn saves labor, conserves fertility, and provides the pigs with a fresh field which is free from parasites.

Experiments have shown that it is advisable to grow some protein-rich supplemental crop, such as soybeans or rape, with the corn for hogging down, or else to allow the pigs access to good pasture. This helps to balance the ration. The pigs should be fed 0.2 to 0.3 lb. per head daily of tankage or an equivalent amount of some other efficient protein supplement, unless protein supplements are unusually high in price. Somewhat more protein supplement is needed if no supplemental crop is grown in the corn. If no protein supplement is fed, it is very important to let the pigs have access to a mineral mixture supplying calcium and phosphorus.

Spring shotes, well grown on pasture and weighing 75 to 130 lbs. at the start, are best for hogging down. Lighter pigs may be used, if a few heavy hogs are put with them to break down the corn. Breeding stock should not be used to hog down corn, as they will get too fat. However, brood sows and their pigs can be turned into the field after the fattened pigs have been removed, to clean up what little corn is left.

Confining the pigs by a temporary fence to an area of the corn field that they can clean up in 2 or 3 weeks may reduce the wastage of corn. However, it adds to the expense and may not be advisable, except with heavy hogs and in very wet seasons.

Corn should not be hogged down until it has reached the glazing stage, because of the great storage of nutrients which occurs up to this time. Owing to the lower yield, it is doubtful whether it is advisable to grow very early varieties, so as to have the crop ready sooner.

In the corn belt the crops most commonly grown in corn for hogging down are soybeans or rape. Soybeans have generally been slightly superior to rape, and they also add nitrogen to the soil, if properly inoculated. Soybeans are planted with the corn at regular planting time, while rape is usually seeded at the last cultivation. In the South, cowpeas are often grown with corn for hogging down, or corn and peanuts are planted in alternate rows.

The area of corn needed for a given number of pigs will depend on the estimated yield. When a protein supplement is fed in addition to the corn, about a bushel of corn a day will be eaten during the hogging-down period by 9 or 10 pigs weighing 75 to 100 lbs. at the start, or by 5 or 6 pigs weighing 150 to 200 lbs.

705. Corn for poultry.—Corn is the chief grain fed to poultry in the United States, and it is unexcelled for this purpose when properly used. While corn is the most common ingredient in poultry rations, it is not essential and can be replaced satisfactorily by other grains. When corn forms a large part of the ration for poultry, it is very important to bear in mind that it is lower than wheat, barley, or oats in protein and also in calcium and phosphorus. Also, the protein in corn is of somewhat poorer quality than in these grains.

When white corn is fed, it supplies no vitamin A value. Yellow corn produces yellow color in the shanks, skin, and body fat and in the yolks of eggs, while white corn does not.

Where grain is fed separately to grown chickens, either as scratch grain or in a hopper, there is little or no advantage in cracking corn, except to force the birds to take more exercise. For use in the mash, corn should be ground, but not too fine, and it should be cracked or ground for chicks. Ear corn is not well suited for poultry. In 3 Ohio experiments corn-and-cob meal ground medium fine was a satisfactory substitute for ground corn in the mash for laying hens or for chicks.[63] With corn-and-cob meal there was a tendency for less feather picking and cannibalism of the layers, though the egg production was slightly lower.

When care is taken to balance the ration properly, corn can satisfactorily form a large part of it. For example, rations containing three-fourths corn have given good results with laying hens and also with chicks.[64] Under usual conditions, however, it is best to include wheat, oats, or other grains in the ration.[65]

Because of its high net-energy value, corn is one of the best feeds for use in rations for broilers and fattening poultry. A large percentage of corn is therefore included in most of the high-energy mashes for broilers. Corn-and-cob meal is not suitable for use in high-energy poultry mashes, because it has much more fiber than does ground corn.

706. Composition of the parts of the corn kernel.—Before discussing the value of the various corn by-products, let us consider the composition of the different parts of the corn kernel.[66] The starchy portion, or endosperm, which forms nearly three-fourths of the kernel, consists mostly of starch and has less than 10 per cent protein and only a trace of fat and minerals.

The hull and tip cap are also composed largely of carbohydrates, though containing less starch and about 15 per cent fiber. The horn-like gluten layer, just under the hull, contains about 22 per cent protein, and the germ carries nearly as much protein and about 35 per cent fat or oil.

707. Hominy feed; degerminated corn meal.—In the usual method of manufacturing corn meal for human use and also in making hominy and hominy grits, the germs and hulls are removed from the corn meal, along with fine siftings from the starchy portions. The *degerminated corn meal* thus produced has a more attractive appearance than the entire ground grain and also keeps much better in storage. However, it contains less protein and fat and therefore is of slightly lower value for stock feeding.

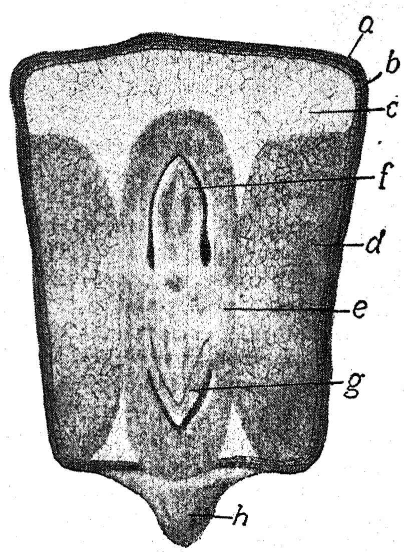


Diagram of a Kernel of Dent Corn

A, hull; b, hornlike gluten; c, floury starch; d, horny starch; e, embryo, or germ; f, embryo stem; g, embryo root; h, tip cap.

Hominy feed (also called hominy meal or hominy chop) is the by-product obtained in this dry-milling process. It consists of a mixture of the corn bran, the corn germs (with or without the removal of part of the fat), and a part of the starchy portion of the kernels.

Hominy feed resembles ground corn in composition and is about equal to it in feeding value for the various classes of stock. It is usually slightly higher than corn in protein, and it contains more fiber than corn and therefore is somewhat more bulky. Unless part of the fat has been removed from the germs, hominy feed will be considerably richer than

corn in fat and will furnish a slightly greater amount of total digestible nutrients.

According to the regulations of the Association of American Feed Control officials, hominy feed should not contain less than 5 per cent of fat.[67] Most samples of hominy feed analyzed by the state feed control laboratories conform to this regulation. These have an average fat content of 6.5 per cent. A few samples fell below the limit, having an average of only 4.6 per cent fat.

708. Value and use of hominy feed.—Hominy feed, often called merely "hominy," is a popular dairy feed. In Pennsylvania experiments hominy feed was practically equal in value to ground corn for dairy cows.[68]

In experiments with fattening cattle the value of hominy feed per ton has ranged from 90 to 100 per cent of that of corn.[69] For fattening lambs hominy feed has been about equal to shelled corn in value per ton.[70] Hominy feed is also a good substitute for corn in feeding horses.[71]

Hominy feed is a satisfactory substitute for corn in swine feeding, except for the fact that hominy feed which has the usual amount of fat tends to produce soft pork. In 23 experiments pigs fed hominy feed with tankage, meat scrap, or an efficient protein supplemental mixture gained 0.1 lb. less per head daily than others fed corn and the same supplements.[72] A trifle more hominy feed than corn was required for 100 lbs. gain, but on account of the somewhat higher protein content of hominy feed, a little less protein supplement was needed. With feeds at usual prices, hominy feed was nearly equal to corn in value, so far as economy of gains was concerned.

In Indiana experiments it was found, however, that if hominy feed having 6.5 per cent fat formed more than half of the ration, the carcasses of hogs tended to be soft.[73] Hominy feed of a low fat content did not have this effect, but its feeding value was appreciably less than that of corn.

Hominy feed is fully equal to corn in poultry rations. In Michigan experiments with broilers and with laying hens the value was even slighty higher than that of corn.[74]

709. Starch and glucose by-products.—In the manufacture of starch and glucose from corn by the wet-milling process, the grain is first softened by soaking in warm water to which sulfurous acid has been added to prevent fermentation. Next, the corn kernels are torn apart in special mills to free the germs. The material is then mixed with water and passed into tanks. Here the germs, which are lighter because of their high fat content, rise to the surface and are removed. The residue is finely ground and the hulls, or bran, separated by cloth sieves.

The liquid which remains contains the starch, the gluten, and very fine particles of fiber. The starch is separated either by centrifugal separators, which are somewhat like the cream separators used for milk, or by an older process in which it settles down in long, inclined troughs. The gluten is then removed from the water by filter presses, and dried. The starch is dried for sale as starch, or is treated with weakly-acidulated water under pressure to convert the starch into sugar, in making corn syrup and similar products. The steep water in which the corn is soaked is condensed by evaporation to recover the soluble nutrients removed from the grain in the soaking process. This residue is called "corn solubles."

In this process the following by-products are obtained: (1) The germs, from which most of the oil is later removed; (2) the bran; (3) the gluten; and (4) the corn solubles. The corn bran is not usually marketed as such, but goes into the gluten feed. The corn solubles may go into the gluten feed or may be used for other purposes, especially in the production of yeast or of penicillin. The protein in corn solubles is of low quality for non-ruminants.[75]

710. Corn gluten feed.—Corn gluten feed, usually called simply "gluten feed," consists of corn gluten meal and corn bran, with or without corn solubles. It may also include part of the corn oil

meal. Usually the manufacturers include just enough corn gluten meal in their corn gluten feed to meet safely a guarantee of 25 per cent protein or some lower percentage. They then sell separately the corn gluten meal in excess of the amount needed to produce the standardized corn gluten feed.

Corn gluten feed of the usual grades supplies about 70 per cent as much digestible protein as linseed meal, and is nearly equal to linseed meal in content of total digestible nutrients. The protein in gluten feed is not of good quality, and therefore gluten feed should not be used as the chief protein supplement for swine or poultry. Gluten feed is not quite so palatable as corn, oats, or wheat bran. It should therefore usually be mixed with such well-liked feeds.

The amount of phosphorus in corn gluten feed will depend on whether or not the corn solubles have been included in it. The average phosphorus content is 0.80 per cent, but it will be considerably lower if the corn solubles are not present. Because of the lime used in neutralizing the corn solubles, gluten feed usually contains more calcium than corn or the other grains.

Gluten feed made from yellow corn, as is usually the case, has a considerably higher vitamin A value than does yellow corn. The color of the gluten feed will show the kind of corn used.

Sometimes molasses is added to corn gluten feed to form *sweetened corn gluten feed.*

711. Gluten feed for dairy cattle.—Gluten feed is used chiefly for feeding dairy cows and is one of the most common protein-rich feeds for this purpose. Though gluten feed is best used as one of the ingredients in dairy concentrate mixtures, it has been fed with satisfactory results to dairy cows as the only or the chief concentrate.

In 5 New York experiments a simple mixture consisting only of corn gluten feed, corn gluten meal, ground corn, and ground oats, with or without molasses, gave as good results, when fed to high-producing dairy cows receiving very little legume roughage, as did a concentrate mixture having much more variety.[76] In another New York trial, when gluten feed formed one-half the concentrate mixture for dairy cows, the results were just as satisfactory as when a smaller proportion was fed.[77] Contrary to statements sometimes made, there is no scientific evidence that a large proportion of gluten feed increases mastitis in dairy cows.

In an Indiana experiment gluten feed was as satisfactory as linseed meal when fed as the only protein supplement to a ration of ground corn, corn silage, and legume hay.[78] Because of the lower protein content of gluten feed, it was necessary to use a larger proportion to balance the ration than in the case of linseed meal.

712. Gluten feed for other stock.—Gluten feed is a fairly satisfactory protein supplement for beef cattle, sheep, or horses. However, it has been inferior to linseed meal or cottonseed meal in the few experiments conducted with fattening cattle or fattening lambs.[79]

Occasionally, gluten feed is lower in price than corn grain. It may then be used as a partial or even a complete substitute for corn for fattening lambs or cattle. Thus fed to fattening lambs, gluten feed was worth only 86 per cent as much as corn per ton in Iowa trials.[80]

Gluten feed is not commonly fed to swine, as it is worth more for feeding to cattle. Because of the poor quality of protein in gluten feed, it is not satisfactory as the chief protein supplement in swine rations, even for pigs on pasture.[81] Gluten feed is rather bulky for swine, and it is not very palatable to them, although they will readily eat a mixture containing 10 to 15 per cent gluten feed. In general, gluten feed is not an economical addition to rations for swine unless the price per ton is less than that of corn or other grain.[82]

Gluten feed is not usually fed to poultry, but it can satisfactorily form about 10 per cent of the ration, replacing part of the other protein supplements.[83]

713. Corn gluten meal.—Corn gluten meal, commonly called "gluten

meal," consists chiefly of the corn gluten separated in the wet-milling process of starch manufacture, with practically none of the hull fragments. It may or may not include corn solubles and may occasionally contain some corn oil meal.

Gluten meal usually has more than 40 per cent protein, averaging 43.2 per cent. It has only 2.3 per cent fat, on the average, and is low in fiber. Gluten meal supplies nearly as much digestible protein as soybean oil meal, but the protein is not of high quality. Therefore gluten meal should not be used as the chief protein supplement for swine or poultry, but should be used with feeds which make good the deficiencies of corn protein.

Gluten meal is a heavy, concentrated feed and is higher than soybean oil meal in percentage of total digestible nutrients, averaging 79.7 per cent. When made chiefly from yellow corn, as is generally the case, gluten meal is even higher than gluten feed in vitamin A value, but it is much lower in calcium and phosphorus. Gluten meal is also very low in riboflavin.

714. Gluten meal for dairy cattle.—Gluten meal is mostly fed to dairy cattle and is a very satisfactory protein supplement for them, when fed in proper combination. Since it is much heavier than gluten feed, it is usually combined with bulkier feeds.

715. Gluten meal for beef cattle, sheep, horses, and swine.—Gluten meal is fed to beef cattle much less frequently than to dairy cows. For fattening cattle it gives fairly satisfactory results when fed as the only protein supplement, if the ration contains a reasonable amount of legume hay. Kansas experiments show that for fattening calves, the best results are secured from gluten meal when it is combined with linseed meal or certain other supplements.[84] However, a mixture of one-half gluten meal and one-half cottonseed meal was not much better than gluten meal fed as the only supplement. Probably a combination of gluten meal and soybean oil meal would give good results, because soybean oil meal has protein of excellent quality.

In 4 New York experiments corn gluten meal produced slightly less rapid gains than linseed meal, soybean oil meal, or ground soybeans, when each of these feeds was used as the only supplement for fattening yearling cattle full-fed corn grain, corn silage, and mixed hay.[85] Also, the selling price of the cattle fed gluten meal was a little lower, because they were not quite so well finished. In these trials the actual value of corn gluten meal was decidedly below that of the other supplements.

On the other hand, for wintering beef calves or yearlings in Kansas experiments, gluten meal was fully equal to cottonseed meal, linseed meal, or soybean oil meal as the supplement to sorghum silage.[86] The difference between the value of gluten meal in these trials and in the New York trials with cattle full-fed corn grain is probably due to the following: Fattening cattle full-fed grain eat relatively little roughage, and the quality of protein in corn grain is poor. Beef cattle being wintered consume mostly roughage, and the quality of the protein in satisfactory roughage, even non-legume, is better than in corn grain. (125)

Apparently because fattening lambs eat a much larger proportion of roughage than do full-fed fattening cattle, gluten meal gives decidedly better results as the only protein supplement for fattening lambs than for fattening cattle.

In 3 New York trials fattening lambs fed gluten meal as the only protein supplement to a low-protein ration made as rapid and economical gains as lambs fed soybean oil meal as the supplement.[87] These supplements were added to a ration of corn grain and corn silage, with little or no legume hay. Lambs fed linseed meal made a trifle more rapid gains than those fed gluten meal and were somewhat more easily kept on full feed. In New York metabolism experiments with growing lambs, the protein of gluten meal had as high a value as that of soybean oil meal or even that of milk. (127) For non-ruminants, the gluten meal protein would be of decidedly lower value.

Gluten meal was satisfactory as a protein supplement for work horses in an Iowa test, but it proved rather unpalatable to them.[88]

In a Kansas experiment with pigs on alfalfa pasture, gluten meal was satisfactory as the only protein supplement to corn, when bone meal was supplied to furnish phosphorus and calcium.[89] For pigs not on first-class pasture gluten meal should not be used as the only protein supplement.

Gluten meal is not quite equal to linseed meal as an ingredient in a trio supplemental mixture for growing and fattening pigs, according to a Nebraska experiment.[90]

716. Gluten meal for poultry.—Gluten meal can be used satisfactorily to replace one-half the meat scrap in poultry rations, if care is taken to provide plenty of calcium, phosphorus, and riboflavin.[91] It should not be used as the chief protein supplement, because of the deficiency in quality of protein. Corn gluten meal tends to increase the yellow color in the shanks and skin of chickens.

717. Corn oil meal or cake; corn germ meal.—The corn germs removed in the wet-milling process are dried, and then crushed and most of the oil removed. The corn oil is used for human food or other purposes. The *corn oil meal* which remains is sold as such, or it goes into corn gluten feed or sometimes into gluten meal, when there is a better market for these products than for the corn oil meal. Occasionally this feed is sold in cake form as *corn oil cake* or in the form of *corn oil flakes.*

Corn oil meal is slightly lower in protein than corn gluten feed. Unless the oil is removed by the solvent process, corn oil meal will be considerably higher in fat than gluten feed and will furnish slightly more total digestible nutrients. The protein is also of somewhat better quality than that in corn gluten feed or corn gluten meal.

Corn germ meal, produced in the dry milling of corn for corn meal, hominy grits, etc. for human consumption, generally goes into hominy feed, and very little is marketed separately. It is similar to corn oil meal in composition and value, but is slightly lower in protein and higher in nitrogen-free extract.

Most of the corn oil meal that is marketed separately is used in poultry or swine rations. It is a common ingredient in mixed poultry-fattening feeds, because of its high water-absorbing capacity. Corn oil meal is also satisfactory as a part of the concentrate mixture for dairy cattle, beef cattle, sheep, and horses.

Corn oil meal or corn germ meal should not be fed as the only protein supplement for swine [92] or poultry, but should be used in combination with supplements that furnish protein of better quality. Pigs on good pasture make fair gains when fed corn and corn germ meal, but the corn germ meal is worth little or no more than corn, ton for ton. Corn oil meal or corn germ meal is best used in swine feeding when tankage, meat scrap, or fish meal forms at least one-half of the protein supplement.

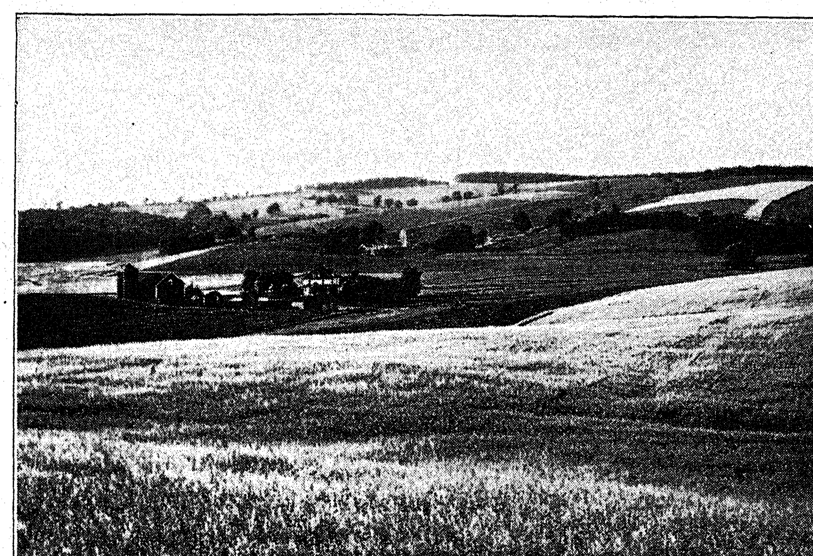
Adding corn oil meal or corn germ meal to a ration of corn and tankage did not increase the rate of gain in experiments with pigs in dry lot or on pasture. In 7 dry-lot experiments, each 100 lbs. of corn oil meal or corn germ meal replaced 42 lbs. tankage plus 45 lbs. corn.[93] In 6 pasture trials, 100 lbs. of corn germ meal replaced 46 lbs. tankage and 13 lbs. corn.[94] Corn germ meal did not produce quite as good results as linseed meal in 3 Wisconsin trials, when it was substituted for linseed meal in the trio supplemental mixture for pigs.[95]

When corn oil meal or corn germ meal have occasionally been lower in price per ton than grain, they have been used as a substitute for part of the grain in swine feeding. The results are best when these feeds do not form more than about one-fourth of the ration. Thus fed, corn oil meal or corn germ meal will be of slightly higher value per ton than corn.[96] If fed in too large amounts, these feeds may cause scours, or make the ration less palatable.

718. Corn bran.—Corn bran consists of the outer coating of the corn kernels, including the hull and the tip cap, with little or none of the starchy part of the germ. Very little corn bran is marketed as such, since it usually goes into gluten feed. Corn bran does not resemble wheat bran in composition, for it does not contain appreciably more protein than corn grain. It has nearly as much fiber as oats and furnishes about as much total digestible nutrients.

As would be expected from its composition, corn bran was decidedly inferior to ground corn as the carbohydrate feed for chicks in a Philippine test.[97]

719. Corn molasses.—Corn molasses, or hydrol, is a by-product in the manufacture of corn sugar from corn. It is usually somewhat higher than cane molasses in sugar, but is extremely low in protein. Experiments have shown it to be about equal to cane molasses in value, though it may be less palatable to stock.[98] Also, it is very viscous in cold weather.



OATS RANK NEXT TO CORN IN IMPORTANCE FOR FEEDING

Oats are an important grain crop in nearly all our states and are used for livestock feeding.

III. OATS AND THEIR BY-PRODUCTS

720. Oats as a feed.—Oats (*Avena sativa*) rank third in acreage among the cereals in the United States and are next to corn in importance for stock feeding. About three-fourths the acreage is in the North Central States, but oats are an important grain crop in nearly all the states. Where barley thrives, oats are sometimes grown in combination with it for stock feeding, as the mixture often produces a greater weight of grain.

Oats are one of the most popular stock feeds. Because of this popularity they are often higher in price, considering their actual feeding value, than the other grains which are available. Oats contain nearly as much protein as does wheat, averaging 12.0 per cent except in the Pacific Coast states. They have even more fat than does corn. Because of their hulls, oats have 11.0 per cent fiber, and they supply only 70.1 lbs. total digestible nutrients per 100 lbs., in comparison with about 80 lbs. for wheat or corn.

Oats have the same general nutritional deficiencies as the other cereals. (680) The protein is not of good quality, though probably superior to that in corn. Oats are low in calcium and only fair in phosphorus, though containing more of these minerals than does corn. Oats lack carotene and vitamin D and are low in riboflavin and niacin.

There is a great variation in the proportion of hulls in oats and consequently in their feeding value. On the average, oats contain about 30 per cent of hulls, and the standard weight per bushel is 32 lbs. Light-weight oats may be over one-half hulls, while there may be only 24 per cent of hulls in very heavy, plump oats. Oats that are high in hulls are ob-

viously low in digestible nutrients and therefore inferior in feeding value. Certain varieties grown extensively in the South and on the Pacific Coast have heavy, coarse hulls, and the kernels bear awns. This causes the weight per bushel to be low.

In buying ground oats on the market one must be careful to secure a satisfactory grade. Sometimes ground oats are made from oats of very low grade and consequently are considerably higher in fiber and lower in protein and fat than oats of good grade.

Clipped oats have been run through an oat clipper, which clips off the pointed ends of the hulls, thus increasing the weight per bushel and lowering the fiber content.

Bleached oats have been bleached by the use of sulfur or other chemicals to whiten the grain and improve the appearance. This does not increase their feeding value and may even be deleterious.

Hull-less oats, varieties from which the hulls are removed from the kernels in the threshing process, have been grown but little in this country, as the ordinary kinds with hulls have yielded much more. Recently, the South Dakota Station has produced a rust resistant variety of hull-less oats which in certain areas yields as great a weight of kernels, not including hulls, as varieties with hulls.[99] The feeding value of hull-less oats and of hulled oats (oat kernels with the hulls removed) is discussed later in this chapter. (729)

721. Oats for dairy cattle.—Oats are a most popular dairy feed, for they are very palatable, they are bulky, and they are somewhat higher than corn in protein. Experienced dairymen commonly include some ground oats in the concentrate mixture for cows and other dairy cattle, unless the price per pound is appreciably higher than that of the other grains. Oats have a higher value for dairy cows in comparison with corn than would be expected from the content of total digestible nutrients.[100] Ground oats are worth fully 90 per cent as much as ground corn for cows, and may equal corn in value when used to give bulk to a heavy concentrate mixture.

Oats should be ground to a medium fineness or crushed for dairy cows. When whole oats are fed, there is nearly as great a loss in unchewed kernels passing through the digestive tract as there is in the case of shelled corn.[101] It is not necessary to grind oats for calves up to 8 or 9 months of age.

722. Oats for beef cattle.—Because of the hulls, oats are worth less per ton than corn, if they form any large part of the concentrates for fattening cattle. Oats are often included in the grain mixture when cattle are being started on feed, but are usually omitted when the cattle are safely on feed, or at least during the latter part of the fattening period. Oats are popular as part of the concentrates for breeding cattle, for they have somewhat more protein and minerals than corn, and their bulk is no disadvantage for such cattle.

Experiments have shown that, except for calves up to about a year of age, it pays to grind oats for beef cattle, even when they are followed by pigs. Medium-fine grinding was preferable to very fine in Indiana tests.[102] In fact, the very finely-ground oats were not so valuable as whole oats. There has been no benefit from grinding oats for fattening calves up to about a year of age.[103]

When ground oats are fed as the only grain or even one-half the grain allowance to fattening cattle, they have been worth only about 85 per cent as much as corn per ton, and sometimes even less.[104] Ground oats may more nearly approach corn in feeding value for fattening cattle when they do not form more than one-third of the grain mixture.[105] Oats are also worth more for breeding cattle or for young stock being wintered than for fattening cattle. In 3 Oklahoma trials ground oats were fully equal to ground corn for wintering beef calves fed grain, cottonseed cake, silage, and ground limestone.[106]

Ground oats supply about as much total digestible nutrients as does ground snapped corn, and they proved fully equal to this feed for fattening cattle in

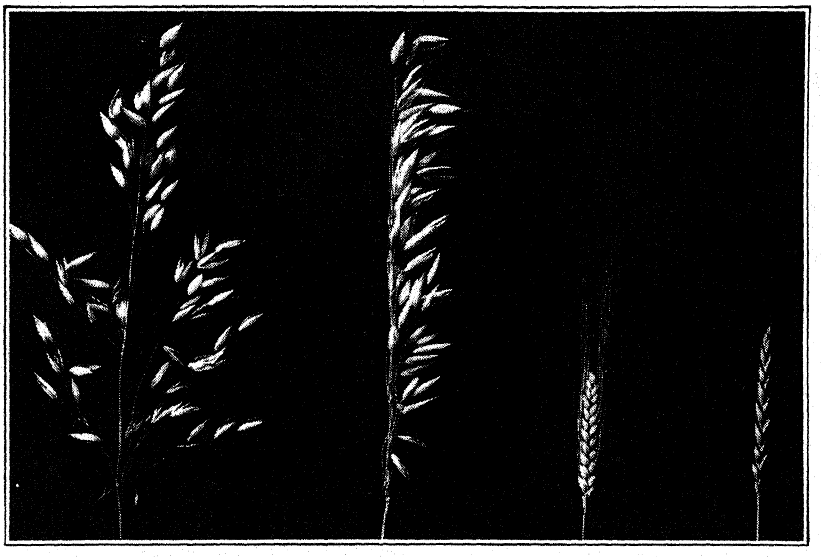
2 Florida tests, when replacing half the corn in the ration.[107]

In experiments in which ground oats have been directly compared with ground barley as the only grain for fattening cattle, the gains on oats have been nearly as rapid, on the average, but ground oats have been worth only about 86 per cent as much as ground barley.[108]

723. Oats for sheep.—Oats are well liked by sheep and are extensively used for the breeding flock, for young lambs, and for starting fattening lambs on feed. When oats are fed to fattening lambs, the proportion is generally reduced gradually as the feeding progresses. After the lambs are on full feed, the oats are usually omitted or only a small proportion is fed, along with heavier grain, such as corn or barley.

However, good-quality, heavy oats may be successfully fed as the only grain throughout the fattening period. With oats as the grain, lambs can be gotten on full feed more rapidly without danger of digestive disturbances than when heavier grain is fed. After the lambs are on full feed, they should be given all the oats they will eat, for it must be borne in mind that oats are much less concentrated than corn or barley.

In 6 Indiana experiments in which oats were thus fed in comparison with shelled corn, the gains were a trifle more rapid on oats and the lambs were as well finished as on corn.[109] While the oat-fed lambs ate more grain, they ate considerably less legume hay and silage. Considering this saving of roughage, oats equalled shelled corn in value per ton.



HEADS OF OATS, EMMER, AND SPELT

From left to right: 1, variety of oats with open or spreading panicle; 2, side oats; 3, emmer; 4, spelt.

In experiments where lambs have been fed approximately equal amounts of oats or of corn, the lambs fed oats have gained less rapidly than those receiving corn, and oats have been worth decidedly less per ton than corn. In 12 tests of this kind lambs fed oats as the only grain gained 0.33 lb. per head daily, in comparison with 0.37 lb. for those fed corn, and the oat-fed lambs required somewhat more feed per 100 lbs. gain.[110] Not considering the less rapid gains on oats, each 100 lbs. of this grain equalled in feeding value only 85.4 lbs. corn,

minus 0.3 lb. protein supplement and 10.5 lbs. hay or hay equivalent in hay and silage. At usual prices, this would make oats worth about 80 per cent as much as corn.

Oats, fed as the only grain, have been more nearly equal in value to barley for fattening lambs in experiments where these grains have been compared, and in some tests have been fully equal to barley.[111] When lambs are gotten on feed rapidly with oats and then fed all of this grain they will eat, it is probably safe to estimate that oats will be worth at least 90 per cent as much as barley. Light-weight oats are, of course, worth much less than heavy oats.

Oats are a popular concentrate for pregnant ewes or ewes nursing lambs. Because of the lower net-energy value of oats, it will require somewhat more oats than corn or barley to keep the ewes in proper condition, but less roughage will be eaten. In Indiana trials each 100 lbs. of oats was equal to 62 lbs. corn plus 43 lbs. hay for ewes nursing lambs.[112]

It is unnecessary to grind oats for sheep. On the average, fattening lambs have made more rapid and economical gains on whole oats than on ground oats.[113] Sheaf oats may be fed to breeding ewes in the winter, thus saving the expense of threshing.

724. Oats are the standard grain for horses.—Oats are such an excellent grain for horses that they are the standard with which other concentrates are compared. Because of the bulky hulls, oats are the safest of all grains for the horse. They form a loose mass in the stomach that can be easily digested, while such heavy feeds as corn, wheat, or barley tend to pack, sometimes causing colic. Even if a horse gains access to the grain bin and gorges on oats, there is much less danger of serious digestive trouble than with the heavier grains.

Oats contain sufficient protein so that merely oats and hay from timothy or other grasses make a balanced ration for mature horses, without adding any protein supplement. Since oats are lower than corn or barley in total digestible nutrients, a somewhat greater weight of oats is required to keep work horses in condition. For horses at very hard work a mixture of oats with corn or barley is better than oats as the only grain.

Grinding or crushing oats for horses whose teeth are kept in good condition increases the value only about 5 per cent.[114] If whole oats are mixed with chopped hay or straw, the saving through grinding is even less.[115] For horses with poor teeth and for foals up to 7 or 8 months of age, grinding or crushing oats is advisable. When oats are not combined, sheaf oats (unthreshed oats in the bundle) are an economical feed for horses, since the cost of threshing is saved and much of the straw is used. New or musty oats should not be fed to horses, as they may cause colic.

While oats are unexcelled for horses, both scientific experiments and the experience of farmers have shown clearly that other grains and also combinations of grains and other concentrates may be substituted for oats without injury to the condition, the wind, the endurance, or even the spirit of horses.

725. Oats for swine.—Oats are satisfactory as part of the ration for swine, but they are too high in fiber and too bulky to be the chief concentrate. Ground oats are worth about as much as corn per 100 lbs. when forming a rather small part of the ration, but when fed in large amounts, they are worth much less than corn, barley, or wheat. Heavy oats, containing a small percentage of hulls, are much better for swine than light oats and may satisfactorily form a somewhat larger part of the ration. Since oats are higher than corn in protein, a little less protein supplement is needed when part of the corn is replaced by oats.

For growing and fattening pigs oats should generally form not more than one-third and preferably not more than one-fourth of the ration. In 20 experiments with pigs in dry lot, when ground oats was fed as not over one-fourth of a well-balanced ration to replace part of the corn, the rate of gain was increased a trifle.[116] Each 100 lbs. of oats replaced enough corn and protein sup-

plement to make the value of the ground oats just about equal to that of corn per 100 lbs.

Oats apparently have a lower value for pigs on pasture, probably because pasture forage itself is bulky. In 9 experiments with pigs on pasture, when oats were similarly added to corn and protein supplement they were worth only 82 per cent as much as corn.[117]

If pigs are fed a larger proportion of oats, the gains are usually slower and the oats worth considerably less. Pigs fed ground oats as the only grain with good protein supplements gained decidedly less in 24 trials than others fed corn and supplement.[118] Without considering the slower gain, the oats were worth 79 per cent as much as corn.

Occasionally, when pigs are self-fed corn and tankage or some other protein supplement, free-choice, ground oats are also provided in a compartment of the self-feeder. When this is done, the pigs generally eat very little of the oats.[119] Therefore, if one desires to use oats for pigs, it is best to mix the ground oats with corn or other grain.

For brood sows before their litters are farrowed, ground oats can form one-half of the ration without appreciably reducing the efficiency.[120] By 2 or 3 weeks after farrowing, the proportion of oats should be reduced to one-fourth or one-third, so as to stimulate the milk flow with a more concentrated ration.

Oats should be ground for swine, as grinding generally increases the value of the grain 25 per cent or more. Fine grinding was preferable to coarser grinding in a Canadian trial, but in Indiana trials medium-fine grinding was fully as good as fine grinding.[121] Soaking whole oats does not increase their value appreciably.

When forming a large part of the ration for pigs, oats tend to produce fat which is a little softer than that produced on corn.

726. Oats for poultry.—Oats are desirable in poultry rations because of certain special qualities, even though they rank below corn or wheat in supplying total digestible nutrients or net energy. Because of the hulls, the use of oats in poultry rations tends to prevent feather picking and cannibalism.[122] Also, the hulls seem to provide a factor that improves the growth and feather development of chicks and helps prevent mortality.[123]

Plump heavy oats should be used for poultry since the hulls seem to furnish no net energy for them. If light-weight oats are fed, one should keep the fiber content of the rest of the ration rather low.

According to Ohio studies, good methods of supplying oats to laying hens are to feed whole oats, free-choice in hoppers, in addition to feeding mash separately, or else to mix 20 per cent of whole oats in the mash.[124] Feeding oats in such a manner was of especial importance with chickens that were closely confined.

For laying hens, as much as 40 to 50 per cent of oats gives satisfactory results, if the oats are heavy and plump.[125] However, a considerably smaller proportion is ordinarily used.

In Texas studies it was estimated that for chickens oats of good grade, containing 30 per cent hulls, supplied about 75 per cent as much net energy per pound as did No. 2 corn, and about 80 per cent as much as wheat.[126] When the proportion of oats is not too large, it seems, however, to have a higher relative value than this for laying hens. Thus, in 3 Texas experiments it was concluded that oats were equal to corn for layers, when thus substituted for it, pound for pound.[127]

Usually, not more than 10 to 15 per cent of ground oats is included in starting mashes for chicks. Too large a proportion may cause digestive disturbances. Using a large percentage of ground oats in a ration for broilers decreases the rate of gain. Sometimes rolled oats or feeding oat meal (not including the hulls) is used as an ingredient in the mash for chicks.

727. Corn-and-oat feed.—This feed, also called corn-and-oat chop, ground corn and oats, ground feed, and provender, is extensively used in the eastern

and southern states for dairy cows and especially for horses and mules. In composition it ranges from a mixture of various proportions of good-grade corn and oats to one containing a large proportion of low-grade materials, such as oat hulls and ground corn cobs. The best guide to the purity is the fiber content. When corn-and-oat feed contains over 7 to 8 per cent fiber, it has either been adulterated or made from poor-quality oats.

728. Oat by-products.—In the method now used in making oatmeal for human consumption, the hulls and particles of the oat kernel, or groat, are combined to form the product called *oat mill by-product.* According to the definition proposed by the Association of American Feed Control Officials, this should not have more than 32 per cent fiber.[67] Since *oat hulls* do not generally have more fiber than this, oat mill by-product as now produced evidently consists almost entirely of oat hulls, with only traces of particles of the oat kernels. The feeding value of this by-product is consequently not appreciably higher than that of oat hulls.

Until the milling process was changed recently, the by-product known as *oat mill feed* had about 84 per cent of oat hulls and 16 per cent of fragments of the kernels. Extensive Wisconsin and other experiments showed that such oat mill feed could be used as a substitute for part of the grain ordinarily fed to dairy cows, beef cattle, sheep, and horses.[128] Thus used, this oat mill feed was worth about 30 to 40 per cent as much as corn grain. Used as a substitute for part of the hay, the value of oat mill feed ranged from that of timothy hay to not appreciably more than that of chopped oat straw. The oat mill by-product now produced in this country undoubtedly has a lower value than the former oat mill feed, because it has a smaller percentage of fragments of the kernels.

Oat hulls are a low-grade roughage, since they supply less total digestible nutrients than oat straw or even wheat straw.

Clipped oat by-product (also called "oat clippings") is the by-product obtained in the manufacture of clipped oats. It may contain, according to the definition of the Association of American Feed Control Officials, the light chaffy material broken from the ends of the hulls, and also empty hulls, light immature oats, and dust.[67] It must not have an excessive amount of hulls. This by-product averages 8.8 per cent in protein and has 25.3 per cent of fiber. It is therefore worth somewhat more than oat mill by-product. Clipped oat by-product is chiefly used as an ingredient in certain mixed feeds.

729. Hulled oats; feeding oat meal; steel-cut oats; hull-less oats.—Occasionally oats for feeding are run through hulling machines which grind the grain and remove most of the hulls. Generally not over 85 to 90 per cent of the kernels are recovered in the *hulled oats,* the rest going with the hulls. It takes 155 to 165 lbs. of whole oats to produce 100 lbs. of hulled oats. Hulled oats are a high-grade feed, but usually expensive. They are sometimes used in pig starters or in mashes for chicks. For growing and fattening pigs ground oats are decidedly more economical.

In 9 experiments with growing and fattening pigs, the addition of a limited amount of hulled oats to a ration of corn and protein supplement has increased the rate of gain slightly.[129] Each 100 lbs. of hulled oats (made from 155 to 165 lbs. of whole oats) saved enough corn and protein supplement to equal about 140 lbs. of corn in value. In these trials the oats before hulling were therefore worth decidedly less than corn per pound. Similar results were secured in 2 Illinois tests with weanling pigs, when one-third hulled oats was included in the ration.[130]

Feeding oat meal, a by-product in the manufacture of rolled oats, consists of broken pieces and fragments of the rolled kernels and floury portions of the kernels, with only such quantity of finely ground oat hulls as is unavoidable in the usual process of commercial milling. According to the definition of the Association of American Feed Control Officials, it must not have more than 4 per cent of fiber.[67] *Steel-cut oats* consist of hulled oat kernels that have been cut into pieces. These feeds are generally used in chick mashes or pig starters.

Hull-less oats have the same composition as hulled oats and resemble wheat, except that they have more fat. They are an excellent feed where they can be produced economically.[131]

730. Sprouted oats.—For a time, sprouted oats were used to a considerable extent in the winter feeding of poultry to furnish a green and succulent feed. With the advances in knowledge concerning the importance of vitamins and other factors in poultry nutrition, efficient rations were developed that made the labor and expense of sprouting oats unnecessary. Therefore the practice has been practically discontinued.

It was claimed some years ago that the

feeding of sprouted oats aided in overcoming sterility in dairy cows and heifers that had failed to conceive from repeated services. However, experiments have shown that sprouted oats are not usually beneficial in such cases.[132]

QUESTIONS

1. Discuss the general nutritive characteristics of the cereal grains, considering amount and quality of protein, amounts of calcium and phosphorus, and content of the various vitamins.
2. Discuss the composition and the special nutritive characteristics of corn grain.
3. Compare the feeding value of yellow corn and white corn under various conditions.
4. What various types of corn are grown? Compare the value of flint corn and dent corn; of hybrid corn and the older open-pollinated varieties.
5. What is the approximate upper limit of moisture for safe storage of ear corn in a crib; for safe storage of shelled corn in a bin?
6. How may soft corn be utilized?
7. In what forms is corn grain fed to stock?
8. Compare the composition and nutritive value of corn cobs and of corn grain.
9. How can ground corn cobs be utilized for: (a) Wintering beef cattle; (b) fattening beef cattle; (c) dairy cattle?
10. Discuss the use and value of corn for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry. For each class of stock, state the forms in which corn is usually fed.
11. Discuss the composition of the different parts of the corn kernel.
12. What is hominy feed? Compare the composition and feeding value of hominy feed and corn.
13. Describe the manufacture of starch from corn and name the by-products produced.
14. Of what is corn oil meal composed and what is its usual composition?
15. Discuss the composition and feeding value of corn gluten feed; corn gluten meal.
16. How does corn germ meal differ from corn oil meal?
17. Discuss the composition of oats in comparison with that of corn, and state the classes of livestock to which oats are most commonly fed in your district.
18. Discuss the use and value of oats for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses; (e) swine; (f) poultry.
19. How could you tell from the guaranteed composition whether or not a particular lot of corn-and-oat feed was of good grade?
20. What is the chief by-product in the manufacture of oat meal? Discuss its composition and feeding value.
21. For what classes of stock are oat meal or hulled oats sometimes used?

CHAPTER XXI

THE OTHER CEREALS AND BY-PRODUCTS

I. Wheat and Its By-products

731. Importance of wheat.—Wheat (*Triticum aestivum*) is second only to corn in importance as a cereal in the United States, but most of it is raised for the manufacture of flour and other human foods. Relatively little of the crop is generally fed to livestock. However, wheat is satisfactory for all classes of stock when properly used, and is equal or nearly equal to corn in feeding value. Wheat has been extensively used for stock feeding in this country when unusually low in price, or when there was a shortage of feed grains and a surplus of wheat. Low-grade wheat, not suitable for milling, is commonly fed to stock.

Though wheat itself is not usually fed to farm animals in this country, the wheat bran and middlings secured in milling wheat rank next to soybean oil meal in tonnage among the by-product stock feeds.

732. Wheat as a feed.—Wheat resembles the other cereals in the general nutritive characteristics which have been discussed in the previous chapter. (**680**) The protein content of wheat varies widely, depending on the climate, the type of wheat, and the soil fertility. Hard spring wheat, chiefly from the northern plains states, has an average of 15.8 per cent protein, and hard winter wheat, chiefly from the southern plains states, an average of 13.5 per cent protein. Soft wheat is much lower in protein. Soft winter wheat from the Mississippi Valley and eastward has an average of only 10.2 per cent protein, and soft wheat from the Pacific Coast states only 9.9 per cent.

The amount of protein in wheat is highly important from the milling standpoint, as it indicates the amount of gluten. Since gluten gives wheat dough the tenacity required in bread making, a high gluten content is desired in flour for this purpose. Much wheat is therefore now sold at the central markets on the basis of certified percentage of protein. For making cakes and pastries, soft wheat is preferred, with its lower protein content.

The protein of the entire wheat grain is of relatively poor quality, although it is superior to that of corn. In wheat bran and wheat germ the protein is of better quality than in the rest of the kernel.

Wheat has about as much nitrogen-free extract (nearly all starch) as does corn, and is only slightly higher in fiber. It has only about 2 per cent fat, in comparison with about 4 per cent for corn. Wheat is fully as digestible as corn, and supplies about as much total digestible nutrients as dent corn of No. 2 grade.

Wheat is low in calcium, having only 0.04 per cent. Its average phosphorus content is 0.39 per cent, which is appreciably higher than that of corn.

Wheat is deficient in vitamin A value and in vitamin D. It is a good source of thiamine but is low in riboflavin, like the other cereals. It is much higher than corn in niacin.

Durum wheat, grown extensively in the western part of the northern plains area, has about the same composition and feeding value as the other spring wheat raised there. The standard weight of wheat per bushel is 60 lbs.

Wheat is usually well liked by stock and is frequently fed as the only grain to swine and to fattening cattle and sheep. However, cattle or sheep occasionally go "off feed" or have digestive disturbances when heavily fed on wheat. This can be avoided by mixing wheat with other feeds, such as corn, oats, barley, or bran.

Since the kernels are rather hard and small, wheat should be ground or crushed for feeding to cattle and horses, and also for swine unless they are self-fed. The grain should be ground to only a medium degree of fineness, for wheat ground to a fine, floury meal is less palatable and more apt to form a pasty mass in the mouth.

Low-grade wheat which is not suitable for milling may nearly equal wheat of milling quality in value for stock feeding, if it is not badly molded. The value of salvage wheat or other salvage grain, which has been damaged in elevator fires, will depend on the extent of injury by charring or smoke.

In using wheat as a feed, the fact that it is higher than corn in protein should be borne definitely in mind. Less protein supplement is needed to balance a ration when wheat is the chief grain than in the case of corn.

733. Wheat for dairy cattle.—Ground wheat is about equal to ground corn for dairy cattle and is an entirely satisfactory feed, even for long periods, if fed in a suitable concentrate mixture and in a properly balanced ration.[1] For dairy cows wheat should be ground, not too finely, or crushed, and it is best to mix it with some bulky concentrate, as it is a very heavy feed. Because of its rather pasty nature, the best results are probably secured when wheat does not form more than one-third to one-half of the concentrate mixture. However, wheat has been fed successfully to cows as the only concentrate, with plenty of legume hay for roughage.

Heads of Different Types of Wheat

From left to right: 1, bearded winter wheat; 2, beardless spring wheat; 3, bearded spring wheat; 4, durum, or macaroni wheat; 5, club wheat.

734. Wheat for beef cattle.—When economical in price, wheat may be substituted for other grain in feeding beef cattle. In several experiments, as mentioned later, ground wheat has given excellent results even when fed as the only grain for fattening cattle. However, in other trials wheat has been much less satisfactory than corn as the sole grain.[2] More care is necessary to prevent cattle fed heavily on wheat from going "off feed" than when other grains are used. Also wheat is somewhat less palatable than corn to cattle.

For these reasons other grains, such as corn, barley, or oats, should, if possible, be mixed with ground wheat for fattening cattle, or else it should be mixed with silage or some other bulky feed. Several experiments have shown that on such mixtures as one-half wheat by weight and one-half of these other grains the gains are generally fully equal to those on corn. Also, the cattle have good appetites throughout the fattening period, are not apt to bloat, and do not tend to go "off feed."[3]

If wheat is fed as the only grain by an experienced cattleman, it may be fully equal to corn in value. In 9 trials in which ground or rolled wheat was thus compared with ground or rolled corn, the wheat-fed cattle made nearly as rapid gains as did those fed corn.[4] In these trials wheat would have produced gains at equal cost, if priced 9 per cent higher per ton than corn.

Ground wheat had a similar high value in 6 trials in which it was compared with ground barley as the only grain.[5] The gains were as rapid on wheat as on barley, and less feed was needed per 100 lbs. gain. On the basis of the feed per 100 lbs. gain, wheat was worth about 18 per cent more than barley.

Wheat should be coarsely ground or else rolled for beef cattle. In tests of these methods of preparing wheat for fattening cattle, there has been no consistent difference in favor of either ground wheat or rolled wheat.[6] In comparing the values of corn and wheat for beef cattle, it should be borne in mind that there is no need of grinding corn if pigs follow the cattle, while wheat is not utilized well unless ground. The cost of grinding must therefore be deducted to find the value of whole wheat per ton, before being ground, in comparison with shelled corn. Sometimes this will be partly offset by the fact that wheat is richer than corn in protein. No supplement may therefore be required with wheat, while it may be needed with corn.

While the results with wheat have differed, it can be concluded that when ground wheat is mixed with other grain for fattening cattle, it is fully equal to corn. Frosted or shrunken wheat may give as good results as wheat of good milling grade.

735. Wheat for sheep.—Wheat is a very satisfactory grain for fattening lambs or for the breeding flock. Although wheat is satisfactory as the only grain for fattening lambs, somewhat better results seem to be secured when it is fed in combination with shelled corn, barley, grain sorghum, or oats.[7] Lambs like such mixtures a little better than wheat alone, and there is sometimes less trouble with them going "off feed."

Wheat fed as the only grain to fattening lambs has produced slightly more rapid gains, on the average, than barley.[8] Also, a little less feed was required per 100 lbs. gain by the wheat-fed lambs, and 100 lbs. of wheat were equal in value to 106 lbs. barley plus 7 lbs. hay.

In experiments in which wheat has been compared directly with corn for fattening lambs, it has had a little lower value than we would expect, in comparison with the results of the tests with fattening cattle and pigs. In 18 experiments lambs fed wheat and legume hay gained an average of 0.28 lb. per head daily, while others fed corn and legume hay gained 0.31 lb.[9] The wheat-fed lambs also required slightly more grain and hay per 100 lbs. gain. Considering only the feed required per 100 lbs. gain and not the difference in rate of gain, 100 lbs. of wheat were equal to 90.6 lbs. shelled corn minus 15.0 lbs. hay. With corn at twice the price of hay per ton, this would make wheat worth 83 per cent as much per ton as corn.

Experiments have shown that it does not usually pay to grind or crush wheat for sheep.[10] Indeed, the ground or crushed grain is less palatable to them and in the case of fattening lambs will usually produce less rapid and less economical gains than whole wheat.

736. Wheat for horses and mules.—Wheat is a satisfactory substitute for oats, if ground coarsely or crushed, and mixed with a bulky feed to prevent colic. Thus fed with care, its value per 100 lbs. will be higher than that of oats.

737. Wheat for swine.—Wheat of good quality is well liked by swine, and is even slightly superior to corn in value for them. It produces firm pork of good quality. In 23 experiments pigs fed ground wheat as the only grain, with an efficient protein supplement, gained a little more rapidly than others fed corn in place of wheat.[11] Because wheat contains more protein than does corn, a little less tankage or other protein supplement was required with wheat, but the wheat-fed pigs consumed a trifle more grain per 100 lbs. gain.

In these trials 100 lbs. of ground wheat were equal in value to 96.8 lbs. shelled corn plus 2.9 lbs. tankage or tankage equivalent. With feeds at representative prices, wheat would be worth about 3 per cent more than shelled corn. In 22 other trials ground wheat has produced slightly more rapid gains than ground barley, when fed as the only grain to pigs, and 100 lbs. wheat have been equal to 107.8 lbs. barley plus 2.1 lbs. tankage or tankage equivalent.[12]

When wheat is fed in self-feeders, pigs chew the grain so thoroughly that grinding it does not usually make sufficient saving to warrant the expense.[13] On the other hand, grinding is advisable when wheat is hand-fed, for the pigs are so eager to get their share that they do not chew whole wheat thoroughly. Wheat should not be ground too finely, or it may form a pasty mass in the mouth. Whole wheat should not be soaked as a substitute for grinding, as it is not so well utilized as the dry whole grain.[14]

Wheat generally gives excellent results when fed as the only grain to swine. Occasionally, however, when wheat is thus fed, pigs may show a little more tendency to go "off feed" than when corn or barley is fed. In such cases, it is well to mix other grain with the wheat, for the combinations produce very satisfactory results. When pigs are self-fed both wheat and corn separately, free choice, they may eat 3 to 5 times as much wheat as corn, because they like wheat so well.[15]

Though wheat is somewhat richer than corn in protein, nevertheless it requires the addition of an efficient protein supplement to produce rapid and economical gains, except for pigs on excellent pasture. Wheat is so palatable to pigs that when they are self-fed, free-choice, on wheat and either tankage or fish meal, they do not generally take more of the supplement than they need.

738. Wheat for poultry.—Wheat is preferred to all other grains by poultry, and it is equal or slightly superior to corn in value for them.[16] Even when wheat is more expensive than other grains, a limited amount is often included in poultry rations because of its palatability and to furnish greater variety.

When wheat is low in price, it can be used satisfactorily as a complete substitute for yellow corn, if sufficient vitamin A is provided by other feeds. Ground wheat may also be substituted for wheat bran and wheat middlings in poultry mashes, but it must be remembered that wheat is lower in protein and also in phosphorus. Soft wheat is somewhat more palatable to poultry than hard wheat, when the whole grain is fed.

If laying hens are self-fed whole wheat, free choice with mash, they may eat so much wheat that they will not consume enough of the mash to balance their ration. This may be avoided by feeding the whole wheat in the evening on top of the mash in about the amount that will be consumed at this feeding.[17]

It has been believed by some that the feeding of new wheat, soon after threshing, tends to produce blue comb, or pullet disease. It is therefore best not to feed wheat to poultry until it has dried out and passed through the sweat.

739. Wheat flour manufacture and the milling by-products.—The wheat kernel is covered with brownish bran coatings, which are richer than the entire grain in protein and minerals and also much higher in fiber. Under the bran is the brownish aleurone layer, also rich in protein. The germ, which is at the base of the kernel, is rich in oil, protein, and minerals. The remainder of the kernel consists of thin-walled cells packed

with starch grains. Among the starch grains are the particles of gluten that give wheat dough its tenacity.

In producing flour the miller desires to secure all the starch and gluten possible from the wheat grains, while avoiding the germ and bran. He leaves out the germs because they make a sticky dough and also soon turn dark and rancid, giving the flour a specked appearance. Nor does he use the aleurone layer, as it gives a brownish tint to the flour.

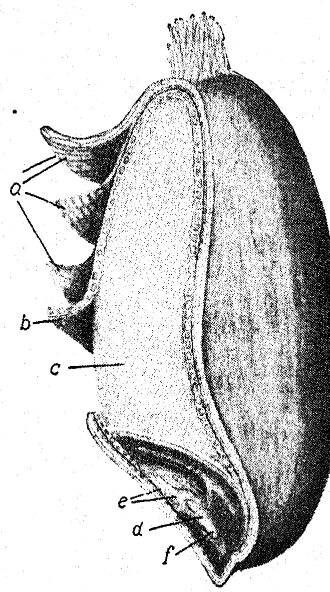

DIAGRAM OF WHEAT KERNEL

A, the bran coats; b, aleurone layer; c, cells filled with starch grains; d, embryo, or germ; e, embryo leaves; f, embryo root.

In modern milling, the wheat is first cleaned and moistened to toughen the bran. Then it passes between pairs of steel rollers, the first pairs of which are corrugated. These rollers gradually break the kernels into pieces, flatten out the bran, and separate the flour from it. After passing through each pair of rollers, the flour is removed by sieves and bolting cloth. Later in the process, the various by-products are separated, all possible flour being recovered at each step in the reduction of the kernels.

The terms used to designate the various by-products differ somewhat in various parts of the country, and also the names of certain of the winter wheat by-products differ from those of the spring wheat by-products. The term *wheat bran* (often called merely "bran") is used for the coarsest by-product, which consists chiefly of the bran layers. For the finer by-products from spring wheat the terms commonly used are *standard middlings, flour middlings,* and *wheat red dog.* In the case of the by-products from winter wheat, the common names are *brown shorts, gray shorts,* and *white middlings.*

In a small proportion of the flour mills, a part of the wheat germ is separated from the other by-products, for the production of wheat germ oil or other purposes. Where part of the germ has been removed, the wheat by-products, especially the middlings, will be lower in vitamin E, and also a little lower in fat.

In the manufacture of white flour, about 71 per cent of the weight of the cleaned wheat goes into the flour and the remainder into the by-products. Of the total by-products, bran and standard middlings each form about two-fifths of the weight, and wheat red dog slightly less than one-fifth.

740. Wheat bran.—Wheat bran, which consists almost entirely of the coarse outer coatings of the wheat kernel, is one of the most popular and important stock feeds. It is highly palatable to stock, and it has a mild laxative effect. Also, it is twice as bulky as oats. Its popularity is due in no small part to these characteristics.

Wheat bran averages 16.4 per cent in protein and 4.5 per cent in fat, and does not usually contain more than about 10 per cent fiber. Wheat bran supplies 66.9 lbs. of total digestible nutrients per 100 lbs., which is slightly less than oats furnish.

The protein of bran is of better quality than that of corn or the entire wheat grain, but it is not so good as the protein in such feeds as soybean oil meal, milk, meat by-products, and fish by-products.

In phosphorus content bran is one of the richest of all common feeds, but

it is low in calcium. It has 1.29 per cent of phosphorus, but only 0.13 per cent of calcium.

Wheat bran has practically no vitamin A or vitamin D. It is rich in niacin and fairly high in thiamine, but rather low in riboflavin, though having more than twice as much as does the whole wheat grain.

The best grades of bran have large clean flakes and contain no screenings. Such bran is often called "pure wheat bran." When bran contains screenings, most states require that the fact be indicated on the feed tags.

"Standard bran," or bran containing screenings, usually sells at 50 cents to $1.00 less per ton than pure bran. Since wheat screenings have much the same chemical composition as wheat bran, there is often no significant difference in composition between bran without screenings and standard bran. Unless bran contains more screenings than usual or unless the weed seeds are of a kind that give it a bitter taste, the difference in price between the two grades probably represents the approximate difference in actual value. However, there may be more danger of introducing noxious weeds on the farm when bran is fed that contains screenings.

Hard spring wheat bran does not differ much in composition from winter wheat bran, but it is slightly higher in fat and furnishes slightly more total digestible nutrients.

Bran and middlings from small mills in which the flour is not separated so completely are a little higher in nitrogen-free extract, a little lower in fiber, and also slightly lower in protein than these by-products from large mills. Such "country mill bran" and "country mill middlings" frequently sell at a slight premium. However, sometimes these terms are used in a misleading manner for any bran or middlings which does not come from a mill in one of the large milling centers.

741. Wheat standard middlings; brown shorts.—*Wheat standard middlings,* usually called "standard middlings" or merely "middlings," are the by-product from spring wheat that consists mostly of fine particles of bran and germ, with very little of the wheat red dog. The similar by-product from winter wheat milling is called *wheat brown shorts,* or sometimes "red shorts." These feeds have about the same composition, except that standard middlings are slightly higher in fiber and also higher in protein and fat than brown shorts. According to the definitions of the Association of American Feed Control Officials, standard middlings must not contain more than 9.5 per cent fiber and brown shorts not more than 7.5 per cent.[18]

Standard middlings are slightly richer in protein and fat than wheat bran and contain more nitrogen-free extract. They are appreciably more digestible than wheat bran and have an average of 77.2 lbs. of total digestible nutrients per 100 lbs. in comparison with 66.9 lbs. for bran. Standard middlings thus supply about 15 per cent more total digestible nutrients and have a correspondingly higher value, except when the more bulky nature and greater laxative effect of bran are desired. Standard middlings are rich in phosphorus, but they are low in calcium, like other wheat by-products.

Middlings supply practically no carotene or vitamin D. They are high in thiamine and niacin, but low in riboflavin.

Standard middlings are used chiefly for swine, calves, and poultry, but may also be fed to other stock in place of bran. For swine and poultry, middlings do not give good results when fed as the only supplement to the grains, because their protein does not correct the deficiencies in the proteins of the grains. Standard middlings and other types of middlings are excellent swine or poultry feeds when part of the protein in the ration comes from such feeds as soybean oil meal, tankage, or dairy by-products.

742. Wheat red dog; wheat white shorts.—*Wheat red dog,* also called "red dog flour," is the spring wheat by-product from the "tail of the mill," consisting chiefly of the aleurone layer, together with small particles of bran, germ, and

flour. The similar by-product from winter wheat is *wheat white shorts,* also called "white middlings." Wheat red dog is slightly higher in protein and fat than white shorts, but otherwise there is little difference in composition.

These by-products are considerably lower in fiber and higher in nitrogen-free extract than standard middlings. They are highly digestible and are even richer than the entire wheat grain in total digestible nutrients. They are fed chiefly to swine, especially young pigs, but are also often used in calf meals, on account of their high digestibility.

743. Wheat feed flour.—Wheat feed flour consists principally of wheat flour, together with fine particles of wheat bran, wheat germ, and the material from the "tail of the mill." According to the definition of the Association of American Feed Control Officials it should not have more than 1.5 per cent of fiber.[18]

744. Wheat flour middlings; wheat gray shorts.—*Wheat flour middlings* consist of standard middlings and wheat red dog combined.

The similar by-product from winter wheat is *wheat gray shorts* (also called "gray middlings" or "total shorts"). The average fiber content of flour middlings is 4.3 per cent and of gray shorts 6.0 per cent. Flour middlings and gray shorts are used much like standard middlings, but are especially well suited to young pigs, because they are slightly higher in digestible nutrients than standard middlings or brown shorts.

745. Wheat mixed feed.—Wheat mixed feed consists of wheat bran and the flour middlings or gray shorts. It is often called "mill run." Since wheat mixed feed of good quality contains the middlings, it is somewhat lower than wheat bran in fiber and it is about 5 per cent higher than bran in total digestible nutrients. This is about the usual difference in feeding value, unless bran is desired for greater bulk.

746. Wheat germ meal; wheat germ oil meal.—Certain of the larger flour mills separate some of the wheat germ more or less completely from the middlings and sell the product as *wheat germ meal.* This contains the germs together with some bran and middlings. It has an average of 27.8 per cent protein and 9.2 per cent fat, and is used chiefly in dog foods, mink feeds, and feeds for laboratory animals. Wheat germ meal is rich in vitamin E. Its use to prevent the "stiff-lamb disease" is discussed in Chapter XXXI.

Sometimes much of the fat is removed from the wheat germs, in the production of wheat germ oil. The by-product which remains is *wheat germ oil meal* or *cake.* This is much lower than wheat germ meal in fat and in vitamin E.

747. Palmo middlings.—"Palmo midds" is a by-product in the making of tin plate. The excess of the palm oil used in polishing the tin plate is removed by scouring the plate with wheat middlings (often containing some screenings). This mixture of middlings with a small amount of oil is sold as palmo middlings.

This by-product usually contains 7 to 10 per cent of fat or oil, and is slightly lower in protein than standard wheat middlings. It should be used in the same manner as wheat middlings in stock feeding and is chiefly fed to swine. On account of the rather high oil content, it had best not form more than 20 to 25 per cent of the ration. Also, palmo middlings may contain appreciable amounts of fine tin particles and may consequently be toxic to stock if it forms a large part of the ration.[19] Smaller proportions of palmo middlings are not injurious.

As a feed for pigs, palmo middlings has generally been worth appreciably less than standard wheat middlings or flour middlings.[20]

748. Wheat by-products for dairy cattle.—*Wheat bran* is one of the most popular dairy feeds, and its value for milk production seems to be somewhat greater than would be estimated from its content of protein and digestible nutrients. Bran is usually fed in combination with the grains and with feeds richer in protein, such as the oil meals. It has a higher value when forming not over one-fourth to one-third of the concentrate mixture than when more is fed. On account of its laxative effect and its bulky nature, bran is especially valuable for

cows just before and after calving and for those on official test. It is also excellent for dairy calves and heifers. Bran and oats are often substituted for each other, wholly or partially, in making up concentrate mixtures for dairy cattle.

Wheat mixed feed may be used in place of wheat bran in dairy rations and is worth about 5 per cent more than bran for this purpose.

Standard wheat middlings or *wheat shorts* are satisfactory for dairy cows when forming not over one-third of the concentrate mixture. Though they are not so bulky as bran or quite so palatable, they are slightly higher in protein and are higher in total digestible nutrients. If standard middlings cost no more than bran, they are an economical substitute for part or all of the bran for dairy cows, unless the bulk of bran is desired to lighten the concentrate mixture.

749. Wheat by-products for beef cattle.—The use of *wheat bran* for beef cattle is limited chiefly to the breeding herd and young calves, and bran is excellent as part of the concentrates for such stock. Bran is also sometimes mixed with the grain when fattening cattle are being started on feed. After the cattle are on full feed, the bran is generally replaced by more concentrated protein supplements, such as linseed meal, cottonseed meal, or soybean oil meal. This is because a much larger amount of bran than of these high-protein feeds must be fed to balance a ration. Since bran is bulky and relatively low in total digestible nutrients, the considerable amount needed to balance the ration will lessen the gains of fattening cattle and result in a poorer finish.[21]

In Kansas experiments with calves or yearling steers being wintered on sorghum silage, nearly 2 lbs. of bran per head daily were needed to produce as good gains as were obtained when 1 lb. of cottonseed meal was fed.[22]

Wheat mixed feed may be used for beef cattle in the same manner as wheat bran. *Wheat middlings* or *wheat shorts* are not commonly fed to beef cattle, but may be included in the ration when economical in price.

750. Wheat by-products for sheep.—*Wheat bran* is excellent as part of the concentrates for breeding ewes, as it is laxative and fairly rich in protein. It is also often used as part of the grain mixture for young lambs, and is frequently mixed with corn and other heavy concentrates in starting fattening lambs on feed. It should form no large part of the grain allowance for fattening lambs after they are on full feed, for it is too bulky.[23] When bran is cheaper in price than grain, 10 to 15 per cent can be satisfactorily included in the mixture for fattening lambs.[24] Such combinations are commonly used in fitting sheep for show.

Wheat mixed feed can be used like wheat bran in sheep feeding. *Wheat middlings* and *wheat shorts* are not often fed to sheep. When standard wheat middlings were fed at the rate of 0.35 lb. daily to fattening lambs in a New York trial, there was a tendency for some of the male lambs to develop urinary calculi.[25] (251)

751. Wheat by-products for horses and mules.—*Wheat bran* is one of the most useful feeds for horses and mules, because of its bulky nature and mild laxative properties. If not more freely provided, its use once a week is desirable. When horses are fed grain as the only concentrate on work days, it is a good plan to feed them on Sundays and other idle days a mixture of one-third bran with two-thirds oats or other grain. Bran is excellent as a part of the ration for brood mares, foals, and stallions. When bran is cheap, it is an economical substitute for part of the grain for work stock.

If horses are constipated, a wet mash may be used, which has a more laxative effect than dry bran fed in mixture with other feed. A wet bran mash is prepared by pouring hot water over the bran and letting it stand for a half hour or more before feeding. A wet bran mash should be given at night and preferably before a day of rest.

Though *wheat middlings* or *shorts* furnish more nutrients than bran, they are not so desirable for horses, because of their heavier character. When fed to

horses, they should be mixed with bulky feeds and should not form over one-fourth the concentrates, as they may tend to produce colic if fed in too large amounts.

752. Wheat by-products for swine.—*Wheat standard middlings* and *brown shorts* are popular swine feeds. They produce excellent results when fed with grain and such protein supplements as dairy by-products, soybean oil meal, meat scrap, or fish meal, which supplement the protein of the grains better. When thus fed, standard middlings are worth fully as much or slightly more than corn per pound. Middlings have the highest value for pigs when not over about 1 lb. per head daily is added to a ration of grain and a high-quality protein supplement.

In 20 experiments in which standard middlings were added to a ration of grain and tankage for pigs in dry lot, the addition of middlings increased the rate of gain slightly.[26] On the average, each 100 lbs. of middlings replaced 88 lbs. of corn and 10 lbs. of tankage. When middlings are added to a ration containing alfalfa hay, grain, and a good protein supplement, the rate of gain is not usually increased.[27]

For pigs on pasture, it does not pay to add middlings to such a ration as corn and tankage, unless the middlings cost considerably less per ton than corn.[28] Middlings produce fair gains when fed to pigs on good pasture as the only supplement to grain, but it usually pays well to add a small amount of a more efficient protein supplement.

Middlings should not be used as the only protein supplement to grain for pigs or breeding swine which are not on first-class pasture. On such a ration the results will be unsatisfactory, because of poor quality of protein. Even when pigs not on pasture are fed alfalfa hay in addition to grain, middlings are not very efficient as the only protein supplement. For example, in 3 experiments pigs fed middlings, alfalfa hay, and corn gained only 0.91 lb. a day, while others fed corn and tankage, with or without alfalfa hay, gained 1.30 lbs.[29]

When middlings are occasionally much lower in price per ton than corn or other grain, they may be used as a grain substitute. However, as they are a less concentrated feed than corn, they produce less rapid gains and are worth only about 85 per cent as much as corn for fattening pigs.[30]

Wheat red dog and *wheat flour middlings* are preferred to standard middlings and brown shorts for young pigs, because of their lower fiber content. Wheat flour middlings are worth 12 to 18 per cent more per ton than standard middlings for growing and fattening pigs.[31] Wheat red dog is probably worth slightly more than wheat flour middlings, because of its greater digestibility.

Wheat bran and *wheat mixed feed* are too bulky for growing and fattening pigs. They are, however, satisfactory as part of the ration for brood sows, and are especially useful, because of their bulk and laxative effect, when no legume hay is available for the sows.

753. Wheat by-products for poultry.—The wheat by-products are popular ingredients of mashes for poultry. Because of the popularity of high-energy poultry rations, wheat bran is now used to lesser extent than formerly, but wheat middlings and red dog flour, which are higher in net energy, are used instead. Including wheat feeds in the ration tends to produce more rapid growth and development and better feathering of growing chickens.[32] Wheat feeds help supply B-complex vitamins, including the vitamins necessary, in addition to manganese, for the prevention of perosis, or slipped tendon, in chickens.[33]

Wheat bran is often used in poultry mashes, especially for laying hens. Usually not more than 10 per cent is included in a laying mash.

Wheat standard middlings and *wheat flour middlings* are common ingredients of poultry mashes, both for laying hens and for chicks, the amount usually being limited to no more than 10 to 20 per cent of the mash. Wheat flour middlings are worth somewhat more than standard middlings, because of their higher net-energy content.

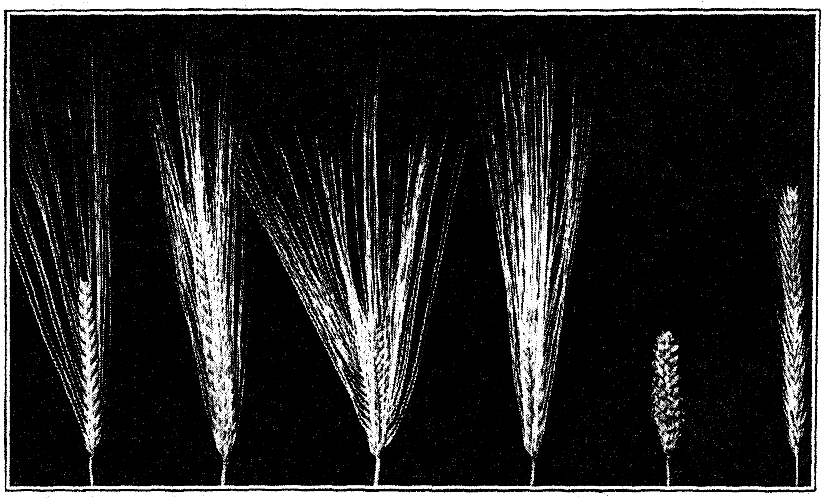
II. Barley and Its By-products

754. Importance of barley.—Barley, which ranks fourth in importance as a grain crop in the United States, is the most widely cultivated of the cereals throughout the world. The crop is especially well adapted to regions of cool summers where the soil is not too sandy but is well drained. It is especially suited to sections with rather scanty rainfall and short growing seasons. Barley does not thrive in a hot, humid climate, and spring barleys therefore do not do well in the southern part of the corn belt.

Barley holds first rank in acreage among the cereals in California, and it is of much importance in the entire district from Minnesota westward to the Pacific Coast. Winter varieties of barley are less hardy than winter wheat and are therefore not suited to cold winter climates. As winter barley matures before the midsummer heat, it does well south of the area where spring barley thrives.

The development of high-yielding smooth-awned varieties of barley by the experiment stations has removed from harvesting barley much of the disagreeableness caused by the barbed beards of the older varieties. In growing barley one should be sure that he has a variety that is well adapted to his locality, for the results from any variety differ widely in various sections. Where barley stripe is a serious disease, it is important to grow a resistant variety.

Often a combination of barley and oats will produce a greater weight of grain per acre than either crop grown alone. The combination is therefore extensively raised in some localities, when the grain is intended for stock feeding and not for market.



Heads of Different Varieties of Barley and of Rye

From left to right; 1, two-rowed barley; 2, common six-rowed barley, or so-called four-rowed barley; 3, true six-rowed barley; 4, California feed barley; 5, beardless barley; 6, rye.

755. Barley as a feed.—Barley is a little higher than oats in protein content, averaging 12.7 per cent except in the Pacific Coast district, where the protein is lower. In certain areas of the northern Plains States and western Canada, the protein content of barley grown without irrigation is appreciably higher than in other districts. For malting, barley medium to low in protein is preferred, but for stock feeding high-protein barley needs less protein supplement.

The hulls form about 15 per cent of the usual types of barley, the best grades of which weigh 46 lbs. or more per bushel. (The legal weight of barley

per bushel in most states is 48 lbs.) Because of the hulls, common barley averages 5.4 per cent in fiber content.

Barley supplies considerably more total digestible nutrients per 100 lbs. than oats and slightly less than corn. Some of the barley varieties grown in the West have thicker hulls and are therefore lower in digestible nutrients and feeding value. Light-weight barley is worth considerably less than heavy, plump barley, as it contains a larger proportion of hull.

Winter barleys and the ordinary spring barleys apparently have about the same composition and value. Hull-less barley resembles wheat or rye in composition, as the hulls do not adhere to the kernels of the threshed grain. However, the yield is considerably less than for the ordinary varieties of barley.

Barley has the same nutritive deficiencies as the other cereals, which have been discussed in the previous chapter. (**680**) The protein is not of good quality, though it is of somewhat better quality than that of corn. Barley lacks carotene and vitamin D and is low in riboflavin. It is rich in niacin, having about 3 times as much as does corn.

Barley should be ground, or crushed, except for sheep or when fed with whole grain to poultry.

Occasionally, cattle bloat when fed barley as the only or the chief grain, especially when the roughage is alfalfa hay. However, the trouble from this source is ordinarily not serious, and it can be avoided by mixing ground barley with ground corn or oats.

Scabbed barley has no injurious effect on cattle, sheep, or poultry, but should not be used for horses or swine. (**672**)

756. Barley for dairy cattle.—Ground or crushed barley is an excellent feed for dairy cattle. When forming from 40 per cent to as much as 60 per cent of the concentrate mixture for dairy cows, ground barley has been equal to ground corn in Arizona, Michigan, North Dakota, and Wisconsin experiments.[34] Some farmers believe barley tends to dry up cows, but there is no evidence at all for this opinion.

Barley should be ground to a medium fineness or crushed for dairy cattle.[35] Too fine grinding is undesirable, as finely ground barley may become pasty in the mouth and consequently unpalatable.

757. Barley for beef cattle.—In those sections of the western and northern states where corn does not thrive, barley is of great importance in beef production. Numerous experiments have shown that fattening cattle will usually make as rapid gains on ground barley, fed as the only grain, as on shelled or ground corn.[36] However, the cattle fed barley have usually sold for a trifle lower price. Also, when pigs follow the cattle, considerably more pork is produced on the shelled corn ration.

Considering all these factors, ground barley has been worth 88 per cent as much as shelled corn for fattening cattle in 14 experiments. The cost of grinding barley must be deducted from this value of ground barley, to find the relative value of whole barley (to be ground before feeding) in comparison with that of corn. If the cattle are not sold on a discriminating market and if no pigs follow the cattle in the feed lot, then ground barley will be worth as much per ton as shelled corn.

Though barley usually gives entirely satisfactory results when fed as the only grain to fattening cattle, sometimes they tire of it during a long fattening period. Also, there is sometimes a tendency for cattle to bloat when fed barley as the only grain, especially with alfalfa hay as the roughage. In either of these conditions it is wise to mix corn or ground oats with the barley. Except in such instances, there is generally no advantage in mixing oats with barley for fattening cattle, after they are on full feed, unless the cost of oats per ton is considerably less than that of barley.

In a Nebraska trial ground barley was fully equal to ground corn for wintering beef calves, and in a Texas experiment ground barley was superior to corn-and-cob meal for fattening cattle.[37]

Barley should be ground medium-fine or rolled for beef cattle. In Arizona tests it was concluded that steam-rolled barley was slightly superior to ground barley, especially for cattle fattening on a heavy allowance of grain.[38]

Trebi barley and ordinary barley were about equal in value in North Dakota tests.[39] Ground hull-less barley is about equal to ground wheat for beef cattle.[40]

758. Barley for sheep.—Barley is a very satisfactory grain for growing and fattening lambs and for breeding ewes, and it is used extensively for them north of the corn belt and in the range districts of the West. Numerous experiments have shown that fattening lambs fed whole barley will gain nearly as rapidly as those fed corn, but they require somewhat more grain and hay per 100 lbs. gain.[41] On the average, good-quality barley has been worth 87 per cent as much as shelled corn in these experiments. Because the rate of gain is a little less rapid on barley than on corn, it will usually take lambs fed barley 3 to 6 days longer to reach a certain degree of fatness.

Although barley contains somewhat more protein than corn, it is relatively low in it, and therefore the ration should be balanced by feeding legume hay or by adding a protein supplement. It is not generally profitable to add a supplement to a ration of barley and legume hay for fattening lambs, for the ration already has enough protein to produce rapid gains.

Barley produces about as satisfactory results when fed as the only grain as when it is fed in combination with corn to fattening lambs. Numerous experiments have shown that for fattening lambs or for breeding ewes it does not usually pay to grind or roll barley, with the possible exception of the hard bald or hull-less barley. Fattening lambs fed ground or rolled barley have usually gained less rapidly and required slightly more feed per 100 lbs. gain than those fed the whole grain.

759. Barley for horses and mules.—Barley is a very satisfactory grain for horses and mules when properly fed.[42] It should be crushed or ground (not too finely). Also, as it is much heavier than oats, it should be mixed with some bulky feed, such as 15 per cent or more of wheat bran or chopped hay, or 25 per cent of ground oats, to avoid danger of colic. Crushed or ground barley is worth about 10 per cent more than crushed or ground oats for feeding work horses, but whole barley is worth less per pound than oats, because horses do not chew the grain completely.

760. Barley for swine.—Barley is an excellent grain for swine feeding and produces pork of high quality, the fat being hard and firm. It should be ground or crushed for swine. In numerous experiments ground barley, fed in properly balanced rations, has produced nearly as rapid gains as corn. However, since barley is less concentrated than corn, because of the hulls, the pigs fed barley require somewhat more feed per 100 lbs. gain. On the average, ground barley of good quality has been worth about 91 per cent as much as corn in these trials. Considering the cost of grinding (which is not necessary in the case of corn), whole barley is worth about 81 to 85 per cent as much per ton as corn for pigs. It is not necessary to mix barley with other grain to secure good results in swine feeding.

Since barley is richer than corn in protein, less protein supplement is needed with barley than when corn is fed. However, pigs that are self-fed, free-choice, on barley plus tankage or other protein supplements often eat decidedly more of the supplement than is needed to balance the ration. It is therefore best to mix the proper proportion of supplement with the ground barley and then self-feed the mixture, instead of self-feeding the grain and supplement separately. Suitable mixtures for dry lot and pasture feeding are shown in Appendix Table VII. Whether or not to feed a protein supplement to pigs fed barley on first-class pasture is discussed in Chapter XXXIV.

The value of barley for growing and fattening pigs is shown by the results of

32 experiments, in each of which one lot of pigs was fed good-quality barley and another lot corn, both lots receiving in addition an efficient protein supplement.[43] In this summary experiments have not been included where the pigs ate an excess of supplement when it was fed free-choice, or where the experimenters fed considerably more supplement than was needed to balance the ration. If just as much supplement is fed with barley as with corn, advantage is not taken of the fact that barley contains more protein than does corn.

On the average, the pigs fed barley gained 1.50 lbs. a day, in comparison with 1.58 lbs. for those fed corn. For each 100 lbs. gain, the barley-fed pigs required somewhat more grain than the corn-fed pigs, but a trifle less supplement (most of which was tankage or meat scrap). In these trials 100 lbs. of ground barley were equal in value to 87.7 lbs. corn plus 2.1 lbs. tankage or tankage equivalent. With feed at representative prices, ground barley would be worth about 91 per cent as much as corn, so far as amount of feed required per 100 lbs. gain was concerned. In 14 similar trials with pigs on pasture, ground barley has likewise been worth about 91 per cent as much as corn.[44] For pigs fed for bacon production in Canadian experiments ground barley had a higher value than this in comparison with corn imported from South Africa. However, no more protein supplement was fed with corn than with barley, and the gains on the corn rations may have been lowered somewhat by a lack of protein.[45]

The saving made by grinding or crushing barley for growing and fattening pigs has differed considerably in various tests, but in nearly all cases it paid to grind or crush the grain. In 29 experiments grinding barley has increased its value 18 per cent on the average.[46] It is best to grind barley to at least a medium degree of fineness, instead of merely cracking it. Very fine grinding does not probably cause sufficient additional increase in value to warrant the greater cost. The pelleting of ground barley is discussed in Chapter XXXIV. (1437)

When barley cannot conveniently be ground, it is often soaked for 12 hours or more before feeding it, but this is a poor substitute. Soaking the grain may produce somewhat more rapid gains, but usually there is little or no saving in the feed required per 100 lbs. gain.[47]

Light-weight barley is worth less than plump, heavy barley, because of the larger proportion of hulls.[48] Trebi barley and the Manchurian varieties have about the same value for swine feeding.[49] Hull-less barley resembles wheat in feeding value.[50] Barley that is badly affected with scab is unsuited for swine. (672)

761. Barley for poultry.—Barley can be substituted for corn or wheat in poultry feeding with satisfactory results, but its value per 100 lbs. is somewhat lower, because of the higher fiber content. In a California trial with pullets the egg production was as high on an all-mash ration containing 68 per cent ground barley as with the same percentage of ground corn, and about the same amount of feed was required per dozen eggs.[51] However, the pullets did not gain as much in weight on the barley ration. In Arizona tests appreciably more feed was required per dozen eggs on a ration having 40 per cent barley than on a similar ration with corn.[52] Fraps of the Texas Station rated barley as having 75 per cent as high a net-energy value as No. 2 corn for chicks.[53]

Since barley lacks vitamin A value, care must be taken to provide a plentiful supply of the vitamin when barley is used to replace yellow corn. Barley produces lighter-colored yolks of eggs than corn and also lighter-colored shanks, skin, and body fat.

Barley is generally rated as being somewhat less palatable than wheat or corn to poultry, but they soon become accustomed to it. When barley is included in the mash it should be ground finely.

Because of the hulls, the growth of chicks is decreased if more than 30 per cent of ground barley is used in a chick starter and more than about 15 per cent in a ration for broilers.[54] Including a large proportion of ground barley in the

mash for baby chicks may cause compaction in the intestines and death losses.

762. Brewery by-products.—In producing beer, the barley is first malted by soaking it in warm water for 2 to 3 days, and then removing it from the water and allowing it to sprout. In this process the amount of diastase, an enzyme that changes starch to malt sugar, increases greatly and some of the starch in the grain is changed to sugar. After sprouting sufficiently, the grain is dried and the small, shriveled roots are separated from the grains. These roots form the feed known as *malt sprouts*. The remainder, consisting of the germinated kernels, forms malt.

The malt is now crushed, water is added, and the mass is kept at the proper temperature for the diastase to change the starch to sugar. Often other grain is added after it has been cooked to gelatinize the starch. When most of the starch has been converted into sugar, the sugar and other soluble matter are extracted to form "wort." This is boiled with hops and filtered, and then yeast is added and the fermentation proceeds.

The residue left after the wort is extracted is called *wet brewers' grains*. These are usually dried and sold as *brewers' dried grains* or *dried brewers' grains*. The spent hops, after drying, are sometimes used in mixed feeds, but have only a low feeding value. The yeast that develops in the fermentation process is sometimes recovered, dried, and sold as *brewers' dried yeast*. (957)

763. Brewers' dried grains.—Brewers' dried grains, often called merely "brewers' grains," contain an average of 27.5 per cent protein, 6.5 per cent fat, 14.2 per cent fiber, and 41.1 per cent nitrogen-free extract. The nitrogen-free extract is largely pentosans, for most of the starch is removed during the malting and extracting process.

Brewers' grains furnish 22.0 per cent digestible protein, but they are rather low in total digestible nutrients, having only 67.1 per cent. They equal corn gluten feed in content of digestible protein but supply considerably less total digestible nutrients. Brewers' grains have decidedly more digestible protein than does wheat bran and equal bran in total digestible nutrients.

Brewers' grains are not very palatable to stock, and therefore they should be mixed with better-liked feeds. They are nearly as bulky as wheat bran, and they keep fairly well in storage.

Brewers' grains are fed chiefly to dairy cattle, especially dairy cows, and produce good results when forming not over about one-third of a concentrate mixture which consists mostly of well-liked feeds. Because of their high fat content, they help to supply the amount of fat that is desirable in dairy rations. (**1020**)

Except when protein supplements cost no more than carbohydrate-rich feeds, brewers' grains are worth somewhat more than wheat bran for dairy cows, because of their higher protein content.[55] On the other hand, they are less valuable than corn gluten feed. In a Pennsylvania test, brewers' grains containing not more than 6 per cent of spent hops were practically equal in palatability and value for dairy cows to brewers' grains containing no spent hops.[56]

In addition to the use of brewers' grains as a protein supplement, they may be used to replace part of the grain in rations for dairy cattle, beef cattle, sheep, and horses, if they are decidedly lower in price per ton than grain. Fattening lambs fed a mixture of one-third brewers' grains and two-thirds shelled corn in 3 New York trials gained as rapidly as others fed corn supplemented with a mixture of linseed meal and cottonseed meal.[57] The brewers' grains saved sufficient corn and supplement to be worth about 98 per cent as much as shelled corn. When only enough brewers' grains were fed, along with corn, to balance the ration, the results were also excellent, and the brewers' grains were worth about three-fourths as much as the mixture of linseed and cottonseed meal.

In an Illinois test, when fattening calves were fed 3.0 lbs. of dried brewers' grains per head daily as a substitute for all the soybean oil meal and some of the

corn in a ration, the gains were slightly reduced.[58] In this test brewers' grains, thus fed, were worth only 55 per cent as much as corn.

Brewers' grains are sometimes an economical substitute for part of the oats in horse feeding, being about equal to oats per pound.[59] Because of their bulkiness, brewers' grains are not usually fed to swine. Even 20 per cent of brewers' grains in the ration for pigs has not given good results.[60]

764. Wet brewers' grains.—Because of their watery, perishable nature, wet brewers' grains are usually fed near the brewery. They are commonly sold by the bushel, as the value per ton varies widely, depending on how well the water has drained out. A bushel of wet grains is equal to about 11 to 13 lbs. of the dried grains. In general, it will take nearly 4 lbs. of the wet grains to equal 1 lb. of dried grains.

To avoid spoilage it may be necessary to haul the wet grains from the brewery every day or two in summer and twice a week when cooler. They may be kept longer by storing in tight barrels, tanks, or pits. Each layer should be tramped thoroughly and sprinkled with salt at the rate of about 1 lb. per 100 lbs. In feeding the wet grains, the mangers and containers should be kept clean and free from any spoiled material.

Wet brewers' grains may be fed to dairy cows at the rate of 20 to 30 lbs. per head daily to replace an equal weight of silage, or as a substitute for part of the concentrates (at the rate of 4 lbs. of the wet grains for 1 lb. of the concentrate mixture). To avoid any tainting of the milk, they should be fed after milking, rather than before, and they should not be stored in the stable. The wet grains may also be fed to other classes of stock, as in the case of the dried grains.

765. Malt sprouts.—Malt sprouts are similar in composition to brewers' dried grains, except that they have much less fat. They are about as bulky as brewers' dried grains, and they supply slightly more total digestible nutrients. Malt sprouts are somewhat bitter and are unpalatable if fed alone. Doubtless for this reason, they are used mostly as an ingredient in mixed feeds, especially for dairy cattle. They are entirely satisfactory for this purpose when used in moderate amounts and are often an economical source of protein and total digestible nutrients. Malt sprouts are often included with the brewers' dried grains, and the mixture sold as brewers' dried grains. The malt sprouts will form only about one-tenth of such a mixture.

Because of the lack of palatability, it is preferable not to include more than about 10 to 15 per cent of malt sprouts in a concentrate mixture for dairy cows or other stock. Feeding too large an amount to dairy cows is said to give the milk a bitter taste. Since malt sprouts swell greatly when they absorb water, they should be soaked for several hours before feeding, if cattle or horses are given more than 2 lbs. per head daily.

In Europe horses are sometimes fed as much as 6 lbs. of malt sprouts per head daily; cattle, 3 lbs.; and sheep, 0.75 lb.

In recent Canadian trials including malt sprouts in a ration for growing pigs increased the rate of gain and decreased the amount of feed required per 100 lbs. gain.[61]

766. Spent hops.—The spent hops, left after the wort has been boiled with hops and filtered, are sometimes dried and used for feed or for fertilizer. They contain not only the hop residue, but also some protein precipitated from the wort in the boiling process. Though they have 20 per cent of protein or more, the digestibility of the material is so low that the product is of doubtful value as a feed.[62] Also, the spent hops are bitter and unpalatable to stock and therefore only a small proportion can be included in a mixture of better-liked feeds.

767. Barley feed; barley mixed feed; barley hulls.—In the manufacture of pearled barley for human food, *barley feed* is secured as a by-product. This consists of the hulls and the outer coats of the kernels. A by-product called *barley mixed feed*, which has about the same composition, is secured when barley flour is manufactured. This should contain not only the hulls but also all the middlings from the kernels. Usually there is but a very small amount of these feeds available in this country. A good grade of barley feed, containing 11 per cent fiber, was worth nearly as much as wheat bran for dairy cows in a Wisconsin trial.[63] For fattening pigs, barley feed was worth 17 per cent less per ton than ground barley.

Barley hulls, sometimes erroneously called barley bran, consist almost entirely of the hulls. Barley bran containing 27 per cent fiber was worth only two-thirds as much per ton for dairy cows as wheat bran in another Wisconsin trial.

768. Malted barley.—It was once believed that the malting of barley increased its value for feeding. Early experiments showed,

however, that a given weight of barley is worth more than the amount of malt and malt sprouts that can be made from it.[64] This is because of the loss of nutrients in the steep water and in the oxidation of nutrients in the germinating process. The use of malt for stock feeding has therefore been practically discontinued, except that malted barley is occasionally used in calf meals or as an appetizer in fitting stock for show.

III. Rye and Its By-Products

769. Rye in the United States.—Though rye (*Secale cereale*) is one of the chief cereals of northern Europe, it is not grown extensively in this country, except in the northern plains. Though it repays good treatment, rye does better than the other cereals on poor or very sandy land.

Practically all the rye grown in the United States is winter rye, which is even more winter-hardy than wheat. In tests in certain districts of the northernmost states, winter rye has led the cereals in average weight of grain produced per acre, even on good soil.

As a winter cover and pasture crop, rye is often grown in certain sections of the South and to a lesser extent in other districts. Its value for pasture during the fall, winter, and early spring has been discussed in Chapter XVIII. (583)

770. Rye for stock feeding.—Rye grain is raised chiefly for bread-making in Europe and is also used largely for this purpose in this country. However, a considerable part of our crop is fed to livestock.

Considering only its chemical composition, we should expect rye to equal wheat in feeding value, for the composition of these grains is very similar. However, even when rye is not appreciably contaminated with ergot, it is usually less palatable to stock than the other grains. Also, when fed as the only concentrate or in too large amounts, it is more apt to cause digestive disturbances.

Rye should therefore be fed with due care and preferably as only part of the concentrates. The grain should not be fed until it has conditioned, or passed through the "sweat" when stored after threshing. Rye that is appreciably contaminated with ergot is unpalatable to stock, and it may even be dangerous if it contains too much of this poisonous substance.

Rye is nearly as heavy a grain as wheat, the weight per bushel being about 56 lbs.

For dairy cows rye had best form not more than 40 to 45 per cent of the concentrate mixture. Thus fed, ground rye has been equal or nearly equal to ground barley or ground corn.[65] Large allowances produce a hard, dry butter, but the butter was satisfactory in a Montana trial when rye formed 40 per cent of the concentrate mixture.[66] Rye should be ground, not too finely, or crushed, for dairy cows.

Though ground rye has given good results in some trials when fed as the only grain to fattening cattle, it is preferable to mix it with corn, oats, or barley. Steers fed ground rye and alfalfa hay in 4 experiments gained nearly as rapidly as others fed shelled corn and alfalfa hay.[67] On the basis of the amount of feed for 100 lbs. gain, rye was fully equal to corn. Like wheat, rye should be ground coarsely or rolled for beef cattle.

Rye is apparently liked better by sheep than by most other stock. When fed as the only grain to fattening lambs, it has produced as good results as barley or wheat in Minnesota and Nebraska tests.[68] Feeding rye as the only grain gave about as good results as using a mixture of half rye and half barley, corn, or oats. There is no advantage in grinding rye for sheep.

Rye is apt to cause digestive disturbances if fed as the only grain to horses, or if the change to rye is made abruptly. It is satisfactory for horse feeding when it forms not more than about one-third of the concentrate mixture and if mixed with oats or some other bulky feed. Rye should be crushed or ground coarsely for horses.

The results secured from rye in swine feeding differ widely.[69] Sometimes pigs make good gains when fed ground rye as the chief grain, but often rye produces poor results, especially with young pigs, when it forms most of the ration. When pigs do well on rye, the feeding value of rye is about equal to that of barley, and the quality of the carcasses is good.

Because of the poor results that are often secured when rye is fed as the only grain, it had best be mixed with at least an equal weight and preferably a larger proportion of other grain, such as corn, barley, oats, or wheat. Rye gives more uniformly good results when fed to pigs on pasture than to those in dry lot. Adding well-cured alfalfa hay to the ration of rye-fed pigs in dry lot is beneficial. A protein supplement should be fed to balance the ration when rye is the chief grain, except perhaps for pigs on good pasture which are over 75 to 100 lbs. in weight. Unless the cost of grinding is unusually high, it pays to grind rye for swine. Rye should be avoided in feeding pregnant sows.

The unsatisfactory results sometimes reported with rye for swine feeding may have been due in some cases to ergot in the rye. However, poor results have been secured even when rye contained no appreciable amount of ergot. Swine have a pronounced dislike for rye that has any marked amount of ergot and eat much less of it than they would otherwise.

Rye is not commonly fed to poultry, as the other grains are more palatable and otherwise superior. Also, rye is too laxative when it forms a large part of the ration. However, rye is usually satisfactory for growing pullets and laying hens if it forms not more than about 20 per cent of the ration.[70] It is best to include the rye in ground form in the mash, because whole rye is not palatable to chickens.

Rye should not be used for chicks during the first week. After this, 5 per cent of ground rye can be included in the mash, and the proportion increased gradually up to 20 per cent by the seventh week. If much rye is fed to chicks, the droppings become so sticky that they ball up on the toes.

771. Rye feed; rye middlings.—All the by-products obtained in the milling of rye for flour are usually combined and sold as *rye feed* or sometimes as *rye middlings,* instead of being marketed separately as bran, middlings, and red dog flour. Apparently, there is little difference between the feeds now sold in this country as rye feed and as rye middlings.

These rye by-products are lower than standard wheat middlings in protein. They furnish slightly less total digestible nutrients than do standard wheat middlings, but somewhat more than wheat bran. They are, however, less palatable than wheat bran, and hence should be mixed with better-liked feeds. For dairy cows, beef cattle, sheep, or swine these rye by-products are a satisfactory partial substitute for wheat bran or wheat middlings, but the amount had best be limited to 15 to 25 per cent of the concentrate mixture. They can also be used to the extent of about 20 per cent in mashes for pullets or hens.

IV. The Sorghums

772. Grain sorghums.—It has already been pointed out in Chapter XVII that in the Plains States from southern Nebraska south to Texas, New Mexico, and Arizona, the sorghums (*Sorghum vulgare*) are of great value for grain and also forage. In the portions of this great area where the rainfall is scanty, they largely take the place of corn, because they are much more drouth resistant. The various types of the sorghums, both the grain sorghums and the sweet sorghums, have been previously described, and their special advantages for grain or for forage pointed out. (543)

As stated previously, the sorghums now grown for grain in the sorghum belt are mostly dwarf combine varieties, which can readily be harvested with a combine. Most of these dwarf varieties were developed by crossing milo with kafir or other taller grain sorghums. Kafir and hegari are also raised for grain to some extent, and sometimes other grain sorghums are grown.

Atlas and certain other crosses between grain sorghum and sweet sorghum are used both for forage and for grain.

Throughout the western portion of the sorghum belt, the grain sorghums are much surer crops than corn, because of their drouth-resistance. Here they usually give decidedly higher yields than corn. In central and eastern Kansas and Oklahoma, the sorghums are superior to corn on poor, thin uplands. Even on the better land in the eastern part of the grain-sorghum belt, it is advisable to use the sorghums as a partial substitute for corn, as insurance against drouth.

The average yield of the grain sorghums in the United States during recent years has ranged from more than 20 bushels per acre to 11 bushels, depending on the rainfall. Yields of 50 bushels or more per acre are sometimes secured under very favorable conditions.

Very recently, hybrid grain sorghums have been developed from inbred strains, somewhat similar to the production of hybrid corn. These new hybrids seem to excel in yield of grain.

The customary basis for selling the seed of the grain sorghums is by the 56-lb. bushel, but the usual weight is about 54 lbs. Grain sorghum heads commonly yield from 70 to 75 per cent of grain on threshing, and it requires 75 to 80 lbs. of sorghum heads to make a bushel of threshed grain. Although the percentage of grain in the entire crop

varies widely with the season and the thickness of the stand, about 30 per cent of the weight of well-cured grain sorghum plants will be grain, on the average. In the case of the dwarf varieties, over half the dry weight may be grain.

When cut for grain, sorghum should not be harvested until the seeds are well matured. Because the hard-coated seeds when apparently dry may contain much moisture, the grain sorghums are especially apt to heat in the bin, unless the grain is well dried.

A Fine Field of Kafir

Because of their resistance to drouth, the grain sorghums are of great importance in regions of low rainfall.

773. Grain sorghums as feeds.—The grain sorghums resemble corn grain in composition and in feeding value. Like corn, they contain about 70 per cent nitrogen-free extract, which is nearly all starch, and they are low in fiber and rich in total digestible nutrients. Most of the grain sorghums have somewhat more protein than does corn, but they have considerably less fat.

The grain sorghums have the same nutritive deficiencies as the other grains. The protein is not of good quality; they are very low in calcium, and they lack vitamin D. Even the yellow-seeded grain sorghums are deficient in carotene. Sorghum grain has about the same content of B-complex vitamins as corn, but it has much more niacin, being as rich as wheat.

When properly supplemented, the grain sorghums are excellent for all classes of farm animals. They are well liked by stock, though they are sometimes slightly less palatable than corn. The seeds of darso, shrock, and sagrain, which are hybrids between grain sorghums and sweet sorghums, are somewhat bitter, due to a high content of tannin. Nevertheless, they give good results when fed to stock.

The seeds of grain sorghums are so small that the grain should be ground for cattle or horses. Otherwise, a considerable percentage will escape mastication. The ground grain is usually called "chop." Grinding for sheep is not necessary, and there is but a small saving in grinding grain sorghum for swine when the grain is fed in a self-feeder on a suitable platform.

Sometimes the unthreshed heads are fed, or the forage, including the heads.

Sorghum head chops, obtained by grinding the entire heads, resembles corn-and-cob-meal in composition and value.

774. Grain sorghum for dairy cattle.—Ground grain sorghum is approximately equal to ground corn for dairy cattle.[71] The ground threshed grain may be fed, or else the entire heads may be ground. Kansas tests show that when whole sorghum grain is fed to cows, one-half or more of the seed may pass through unchewed and hence undigested.[72]

775. Grain sorghums for beef cattle.—In the sorghum belt the grain sorghums largely take the place of corn for beef cattle. Grain sorghum is well liked by fattening cattle, produces nearly as rapid gains as does corn, and is not far below corn in feeding value. Grain sorghum is usually fed to beef cattle either as the ground threshed grain, or as sorghum head chops.

Several experiments have shown that for beef cattle ground grain sorghum is usually worth about 90 to 95 per cent as much as corn. The different varieties of grain sorghum now generally grown do not differ much in feeding value, though the value of milo and the milo-like hybrids is apparently slightly higher than that of kafir or Early Kalo, and appreciably above that of darso.[73]

In Kansas trials with fattening cattle grain sorghum ground to a coarse, mealy texture was utilized slightly better than that ground very coarsely.[74] Rolled sorghum grain was not superior to the ground grain. In 3 Texas experiments with fattening calves, the combined gains of the calves and the pigs following them were fully as large when unground milo was fed, as when the grain was ground.[75] This may have been because the seeds of milo are larger than those of some of the other sorghums.

Sorghum head chops are about equal to ground snapped corn (including husks) in value for fattening cattle and produce nearly as rapid gains as ground threshed sorghum.[76] If one wishes to have the cattle gain as rapidly as possible, it may be best to change to ground threshed sorghum during the latter part of the fattening period.

In Texas experiments there was a greater tendency for urinary calculi to develop in steers fed milo head chops than when fed ground threshed milo.[77]

776. Grain sorghums for sheep.—Experiments have shown that the threshed grains of the various grain sorghums are about equal to shelled corn in feeding value for fattening lambs.[78] Also, there has been no appreciable difference in the value of the different kinds of grain sorghum.

In most of the experiments on grinding grain sorghum for sheep, such preparation has not paid.[79] However, in recent Kansas and Texas trials there has been a slight benefit in grinding or rolling milo or other combine-type grain sorghums for fattening lambs.[80]

Unthreshed sorghum heads have proved equal to the threshed grain in feeding value, considering the actual amount of grain contained, and have produced practically as rapid gains on fattening lambs.[81] In wet weather there may, however, be considerable waste in feeding the unthreshed heads outdoors.

It was concluded in Kansas tests that lambing down a field of ripe grain sorghum is a wasteful practice, if the yield of grain is sufficient to warrant harvesting it.[82] In South Dakota trials, grain sorghums did not produce as much gain per acre when lambed down as did corn.[83]

777. Grain sorghums for horses and mules.—In the regions where they flourish, the grain sorghums are used extensively for feeding horses and mules, and are only slightly less valuable than corn. Sorghum grain should be ground or crushed for horses or mules, and if possible mixed with wheat bran or middlings, for it tends to produce constipation. The grain sorghums may also be fed unthreshed in the heads, or along with the forage.

778. Grain sorghums for swine.—The grain sorghums are excellent for swine and nearly equal corn in feeding value, both for fattening pigs and for

breeding stock. The pork produced by feeding the grain sorghums is equal to that from corn in quality. Numerous experiments have shown that the chief varieties of grain sorghum produce about as rapid gains as corn and the feeding values are about 90 to 95 per cent of that of corn.[84] Sweet sorghum seed and some hybrids which are high in tannin content are less palatable and have less value.

In using grain sorghum as a substitute for yellow corn in swine feeding, it must be borne in mind that sorghum grain does not supply carotene (vitamin A value). Also, milo has even less lysine than does corn. This lack is corrected when it is fed with such protein supplements as soybean oil meal, meat scrap, tankage, or fish meal, which have good supplies of this essential amino acid.[85]

Since grain sorghum has the same nutritive deficiencies as the other small grains and also white corn, brood sows are unable to produce thrifty pigs when fed grain sorghum alone, without a proper supply of protein, minerals and vitamins.[86]

The sorghums should be threshed for swine, instead of being fed in the head.[87] Grinding the heads is a disadvantage, as it forces the swine to eat the fibrous stems of the heads. Also, soaking the heads is inadvisable.

When growing and fattening pigs are self-fed, grinding grain sorghum does not usually increase its value enough to justify the expense.[88] On the other hand, when the grain is hand-fed the pigs are in such haste to get their shares that they do not chew it so thoroughly. Therefore, grinding the grain is then usually advisable. There is no advantage in soaking either whole or ground grain sorghum for swine.

Sometimes ripe grain sorghum is hogged down by turning fattening pigs into the field to harvest the crop. The same methods should be followed as in hogging down corn.[89] **(704)** It may be necessary to restrict the area in which the pigs are feeding, by temporary fencing to get them to clean the grain up properly.

779. Grain sorghums for poultry.—The grain sorghums are nearly equal to corn per pound for poultry, when used in well-balanced rations. When grain sorghum replaces yellow corn in poultry feeding, care must be taken to furnish plenty of vitamin A value in the other feeds. Also, a large proportion of grain sorghum in a broiler ration will produce white skinned and shanked birds, unless enough alfalfa meal or corn gluten meal is included to give the desired yellow color.

Ground grain sorghum can be used in poultry mashes in the same manner as ground corn, and the whole grain can be fed as part of the scratch grain. There are apparently no marked differences in the values of the various grain sorghums for poultry, except that the varieties with white or yellow seeds seem to be more palatable to them. In most of the experiments in which milo, kafir, hegari, and kalo have been fed to chicks or laying hens as part of a well-balanced ration, these grain sorghums have been nearly equal to corn in value.[90]

780. Sorghum gluten meal; sorghum gluten feed.—Starch is produced from grain sorghum in a process similar to that used for corn starch. The by-products, *sorghum gluten meal* and *sorghum gluten feed* resemble corn gluten meal and corn gluten feed in composition, except that the sorghum feeds have somewhat more fat. They are not very palatable to stock and should therefore be mixed with well-liked feeds.

The Texas Station has conducted several experiments to find the value of these sorghum feeds for various kinds of stock.[91] Sorghum gluten meal was nearly equal to cottonseed meal as the protein supplement for dairy cows and equal to cottonseed meal for fattening cattle. For fattening lambs it equalled cottonseed meal with legume roughage, but was worth only 85 per cent as much with non-legume roughage. For pigs it was satisfactory as 30 per cent of the protein supplemental mixture, when combined with feeds that had protein of better quality. For poultry it could be used much like corn gluten meal.

Sorgum gluten feed may be used in rations for cattle or sheep in the same manner as corn gluten feed, except that, because of its low palatability, it had best not form more than about one-third of the concentrate mixture.

781. Sweet sorghum seed.—The seed of the sweet sorghums, or sorgos, contains considerable tannin, which makes it bitter and astringent. Its feeding value apparently differs considerably for the various kinds of stock.

While sweet sorghum seed has been said to have a tendency to dry up dairy cows, ground sweet sorghum seed gave as good results as ground corn in Kansas tests, when forming more than half of the concentrate mixture.[92] Ground sorghum heads also were satisfactory, when making up two-thirds of the concentrates.

In experiments with fattening cattle and lambs, however, ground sweet sorghum seed has often been decidedly inferior to grain sorghum and not worth more than two-thirds as much as corn.[93] Likewise, when fed to pigs in 6 tests, ground sweet sorghum seed has produced much less rapid gains than grain sorghum, and has been worth only about 68 per cent as much as corn.[94] Due to the small size of the seeds, sweet sorghum grain should be ground for all classes of stock except sheep.

782. Broom corn seed.—In harvesting broom corn, which is one of the sorghums, the heads are cut before the seed has fully matured, and the seed is removed from the brush before it is thoroughly dry. This seed has considerable feeding value and may be saved by drying or ensiling. In an Oklahoma test with fattening pigs, ground broom corn seed gave better results when forming one-fourth of the ration than when forming one-half.[95] Thus fed, it was worth 60 per cent as much as corn.

V. Rice and Its By-products

783. Rice; rough rice; chicken-feed rice.—Rice (*Oryza sativa*) is one of the most important cereal crops of the world and forms a large part of the food of Oriental peoples. In this country rice production is important only in Louisiana, Texas, Arkansas, and California. Rice is used almost entirely for human food and is fed to stock only when off-grade or unusually low in price.

The rice kernels are very hard and are enclosed in hard hulls, which have sharp ridges with tooth-like projections. The threshed grain, called rough rice, or paddy rice, is nearly as high as oats in fiber and is even lower than corn in protein. Rough rice may be used as a substitute for other grain in stock feeding. It has the common merits of the cereals as a feed and also the same general deficiencies, including a lack of carotene. Because of the hardness of the kernels, it should always be ground, except perhaps for poultry. The grinding should be fine enough to reduce the hulls to a meal.

For dairy cows and work horses or mules, ground rice has been about equal to ground corn.[96] In 4 experiments with fattening cattle, it produced somewhat less rapid gains than corn and was worth only about 81 per cent as much.[97] Similarly, in 4 experiments with fattening pigs, ground rough rice was worth about 84 per cent as much as corn.[98] It produces firm pork of good quality.

The value for fattening lambs has been lower than for other stock, ranging from 55 to 76 per cent of that of corn, when fed as the only grain.[99]

For laying hens, in rations containing adequate vitamin A from other sources, whole rough rice was satisfactory as 75 per cent of the scratch grain, and in an all-mash ration ground rough rice was a good substitute for ground corn as 35 per cent of the mash.[100]

784. Rice bran.—Rice bran consists of the rice bran and germs removed in milling rice for human food, and it should contain only such quantities of hull fragments as are unavoidable in the regular milling process. Rice bran of good quality averages 12.4 per cent in protein and 13.6 per cent in fat, with 11.6 per cent fiber. It is similar to oats and wheat in protein content, and decidedly lower than wheat bran or middlings. Rice bran supplies protein of considerably better quality than corn. It is rich in thiamine and very high in niacin.

Rice bran is fairly palatable when fresh, but it often turns rancid in storage, because of the high oil content. Thorough heating and drying at the mill improve the keeping quality. Recently, some solvent-extracted rice bran, low in fat, has been produced, which keeps well. Rice bran varies considerably in fiber content, depending on the proportion of hulls present, and sometimes it is adulterated with hulls. In purchasing rice bran, it is safest to buy it only on strict guarantee of composition, and also from a sample that has been examined for rancidity.

Rice bran is fed chiefly to dairy cattle. When forming not more than one-third the

concentrate mixture for dairy cows, it has been approximately equal to wheat bran and worth about 75 to 80 per cent as much as ground corn or milo grain.[101] Too large a proportion of rice bran causes soft butter.

Rice bran may also be used in place of part of the grain for beef cattle or sheep. Its value is two-thirds to three-fourths that of corn, when used as one-third the concentrates.[102]

Rice bran has given good results in swine feeding when forming not more than 25 to 30 per cent of the ration.[103] When thus fed, it has been usually worth fully as much as corn, and sometimes even more. Used in place of wheat standard middlings or wheat shorts, it is worth nearly as much per pound as these feeds.

When rice bran forms a larger part of the ration, it tends to produce soft pork, unless it is solvent-extracted rice bran. When rice bran makes up more than about 30 per cent of the ration for pigs, the rice bran is worth only about 86 per cent as much as corn. Too large a proportion of rice bran is also apt to cause serious scouring of pigs under 75 lbs. in weight.

Rice bran can be used in place of wheat bran or wheat middlings in poultry feeding, if the ration does not include rough rice as well.[104]

785. Rice polishings, or rice polish.—Rice polishings, also called "rice polish," are the finely powdered material obtained in polishing the rice kernels, after the hulls and bran have been removed. They contain as much protein and nearly as much fat as rice bran, have only 2.7 per cent fiber, and supply fully as much total digestible nutrients as corn. Rice polishings are rich in thiamine and especially high in niacin. Though not rich in riboflavin, the content is somewhat higher than in the whole cereal grains. They tend to become rancid in storage, like rice bran, and should therefore be fed when as fresh as possible.

Rice polishings are satisfactory as part of the concentrate mixture for dairy cattle, beef cattle, and sheep. In Arkansas trials they were equal to ground corn for dairy cows when forming one-fourth of the concentrate mixture, but when as much as this was fed soft butter was produced.[105] For fattening cattle rice polishings were worth only 88 per cent as much as corn in 3 Louisiana tests.[106]

Rice polishings have the highest value in swine feeding. Though they have some of the same limitations as rice bran as a swine feed, they have been worth 121 per cent as much as corn when used to replace one-third of the corn for pigs, and 112 per cent as much as corn when forming a larger part of the ration.[107]

Rice polishings tend to produce soft pork, especially when forming more than one-half of the ration for fattening pigs. They are also apt to cause serious scours if too much is fed to pigs under about 75 to 80 lbs. in weight. Rice polishings are entirely satisfactory as part of the ration for brood sows and litters. If the pigs are then grown and finished on non-softening feeds, their carcasses will not be soft.

786. Brewers' rice; rice meal.—*Brewers' rice* consists of the small pieces of broken kernels that are removed from the whole kernels in the milling process. It is used chiefly in the brewing industry, but is sometimes fed to stock. Brewers' rice furnishes about as much total digestible nutrients per 100 lbs. as the grain sorghums or barley. As it may be less palatable than grain, it is best to mix it with well-liked feeds. In 22 experiments with fattening pigs, brewers' rice has been worth about 6 per cent more than corn,[108] but in one test with fattening cattle, it was not quite equal to corn.[109] Brewers' rice produces hard pork of good quality.

Rice meal, according to the definition of the Association of American Feed Control Officials, should be ground brown rice (ground rice after the hull has been removed).[18] The term is, however, used sometimes for entire ground rice, including the hulls. Rice meal is nearly equal to corn for stock feeding.[110]

787. Rice hulls; rice mill by-product.—*Rice hulls* have a very low value as a feed, for they furnish only about one-fourth as much total digestible nutrients as does oat straw, and practically no digestible protein. When there is a serious shortage of roughage, well ground rice hulls may be substituted for a small part of the roughage usually fed cattle, in order to carry them through the period of deficient feed supply.

In Arkansas trials in which ground rice hulls, mixed with the concentrate allowance, replaced 15 to 25 per cent of the prairie hay in a ration for wintering beef steers, fair gains were made, but less than on rations without the hulls.[111] The rice hulls, thus fed, had a very low value per ton in comparison with prairie hay. Unsatisfactory results were secured in Texas experiments with beef steers when rice hulls were used as the only roughage, in place of cottonseed hulls.[112]

It has sometimes been stated that the sharp edges of rice hulls may irritate the

digestive tracts of stock. However, in a Louisiana test no such effect was produced by feeding growing steers a mixture containing as much as 30 per cent ground rice hulls.[113]

Rice mill by-product is the name proposed by the Association of American Feed Control Officials for the entire by-product obtained in the milling of rice, including the hulls, rice bran, rice polish, and broken grains.[18] This is sometimes called "rice mill feed." The fiber content should not exceed 30 per cent. About 60 per cent of such a product would be rice hulls. In an Arkansas trial steers being carried through the winter gained decidedly less on rice mill feed as the only roughage, plus 3 lbs. of concentrates a day, than on prairie hay with the same concentrate allowance.[111] In another Arkansas trial rice mill feed was a satisfactory substitute for two-thirds the prairie hay in a properly supplemented ration for wintering steer calves.

VI. Emmer; Spelt; Millet

788. Emmer and spelt.—Emmer (*Triticum dicoccum*) and spelt (*Triticum spelta*) are close relatives of wheat, but the grain resembles barley in appearance, for the hulls are not usually removed from the kernels in threshing. These grains have never become of any importance in the United States, because the other cereals are more productive in most sections. Three-fourths of the acreage (mostly emmer) is in North and South Dakota.

Emmer is often incorrectly called "speltz" or "spelt." Spelt is grown but little in this country and has been largely displaced by other grains where it was once raised in Europe.

Emmer and spelt closely resemble oats in composition. They may be used in the same manner as oats in feeding the various classes of stock and have about the same value as oats per 100 lbs.[114] The weight of these grains per bushel varies considerably, a common weight being 40 lbs. per bushel.

When a large proportion of the hulls is removed in threshing, emmer will resemble barley more than oats in composition and feeding value.

789. Millet.—The only kind of millet grown in this country as a grain crop is hog millet (*Panicum milaceum*), or proso, also called broom-corn millet. It is the ordinary millet of the Old World, which has been raised since prehistoric times as an important grain crop for human food. The forage types of millet have been discussed in Chapter XVIII.

Hog millet has spreading or panicled heads, wide, hairy leaves, and large seeds. It is not raised for grain to any extent in this country except in the most northern part of the great plains, where the growing season is too short for the grain sorghums. Here it is often grown as a late-sown catch crop, for other cereals will usually outyield it if seeded at the normal time. The yields usually range from 10 to 30 bushels per acre.

Hog millet gives satisfactory results when used as a substitute for other grain. It should always be ground for all classes of stock except poultry. In experiments ground hog millet has been worth from 75 to 90 per cent as much as corn for fattening cattle and lambs; from fully equal to corn to 85 per cent of the value of corn for pigs; and 95 per cent as much as corn for laying hens.[115]

Finely ground foxtail millet seed was fully equal to shelled corn for growing and fattening pigs in a Kansas trial.[116]

VII. Buckwheat and Its By-products

790. Buckwheat.—Buckwheat (*Fagopyrum esculentum*) is not really a cereal but belongs to an entirely different family of plants. It is discussed here because the seed has much the same general nutritive characteristics as the cereal grains. Buckwheat often does better than the small grains on poor or very acid soil, and it is also frequently grown as a late-sown catch crop, because of its short growing season. Buckwheat is raised chiefly for the manufacture of buckwheat flour and other human foods, but it is sometimes fed to stock when the grain is low in price.

The woody hulls of buckwheat form 18 to 20 per cent or more of the seed, and the grain has 10.7 per cent fiber, which is about as much as oats. It has somewhat less protein than oats and only about one-half as much fat, and it furnishes appreciably less total digestible nutrients. It is not so palatable as most of the grains. It should therefore be mixed with well-liked feeds and should preferably not form more than one-third of the mixture.

It is of interest that in recent Arkansas studies with rats it was found that the protein of whole buckwheat or buckwheat flour was of much higher nutritive value than that in other plant products, even soybean oil meal.[117]

Buckwheat should be ground for all classes of stock except poultry. Fed in a

suitable mixture, ground buckwheat is probably worth 5 to 10 per cent less than ground oats for dairy cows or other cattle. In 3 Tennessee trials pigs on pasture gained slightly more rapidly on shelled corn and protein supplement than when ground buckwheat replaced all or one-half of the corn.[118] In these trials ground buckwheat was worth 71 per cent as much per pound as corn. In Canadian trials it was somewhat inferior to wheat or wheat middlings for fattening pigs.[119] Occasionally, buckwheat grain and also the green fodder or straw cause peculiar eruptions and intense itching of the skin. This affects only white or light-colored portions of the hide, and animals are usually thus injured only when exposed to light.

Tartary buckwheat (*Fagopyrum tataricum*), also called "India wheat" or "rye buckwheat," is higher in hull and lower in milling quality and in feeding value than ordinary buckwheat. However, it does better on very poor soil, is more frost-resistant, and yields better under adverse conditions.

791. Buckwheat by-products.—*Buckwheat middlings* are the portions of the buckwheat grain immediately inside the hull, which are separated from the flour in the milling process. They contain 29.7 per cent protein and only 7.4 per cent fiber, and they are about equal to gluten feed or brewers' dried grains in value.[120] They are generally used for dairy cows and are a satisfactory protein supplement when forming not over one-third the concentrate mixture. They may also be used as a substitute for wheat middlings in feeding swine and other stock. They are not satisfactory as the only protein supplement for pigs, but should be combined with supplements like meat scrap or tankage, which provide better protein.[121]

Sometimes buckwheat hulls (which have very little feeding value) are mixed with buckwheat middlings to form *buckwheat feed*. The value of this will depend on the proportion of hulls. If buckwheat feed has 20 per cent fiber, it will be about one-third hulls.

Buckwheat hulls are woody, high in fiber, and exceedingly low in digestibility. Since they supply only one-third as much total digestible nutrients as wheat straw, they have very little feeding value. They should be used for fuel, bedding, or packing, rather than for feed.

QUESTIONS

1. Compare the composition of wheat and corn.
2. Discuss the value and use of wheat for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry.
3. Describe the manufacture of flour from wheat, and state the by-products secured in the milling process.
4. Discuss the composition of: (a) Wheat bran; (b) standard wheat middlings, or brown shorts; (c) wheat red dog, or white shorts; (d) wheat flour middlings, or gray shorts; (e) wheat mixed feed; (f) wheat germ meal.
5. What wheat by-products are chiefly used for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry?
6. Compare the composition of barley and corn.
7. What is the value of barley, compared with corn for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry?
8. Describe the malting process and state the by-products that are produced for feeding.
9. Discuss the composition and use of brewers' dried grains; of malt sprouts.
10. What limitations has rye as a feed for livestock?
11. What is the chief rye by-product? Compare its composition with that of standard wheat middlings.
12. Discuss the composition and feeding value of the grain sorghums, in comparison with corn.
13. If any of the following are of importance in your district, summarize briefly the information concerning their composition and feeding value: (a) Rough rice; (b) rice bran; (c) rice polish; (d) rice hulls; (e) emmer; (f) hog millet; (g) buckwheat; (h) buckwheat middlings.

CHAPTER XXII

OTHER SEEDS AND THEIR BY-PRODUCTS

I. Soybeans, Soybean Oil Meal, and Other Soybean By-products

792. Soybeans.—In the discussion of soybeans as a forage crop in Chapter XVI it has been pointed out that in recent years they have become one of our most important crops. The largest acreage is grown in the heart of the corn belt, but soybeans are also raised extensively southward to the Gulf States. Over 85 per cent of the entire acreage of soybeans is grown for seed, chiefly for the production of soybean oil and soybean oil meal. The average yield of seed per acre is about 20 bushels of 60 lbs. each.

Soybeans are the richest in protein of all the common seeds used for feed, averaging 37.9 per cent. They are also high in fat, having 18.0 per cent, and they are rather low in fiber, with 5.0 per cent. In total digestible nutrients, they rank even above corn, chiefly because of their high fat content. Most black-seeded varieties of soybeans are somewhat lower in fat than the yellow-seeded varieties common in the corn belt.

Soybeans are rather low in calcium, with only 0.25 per cent. They have much less phosphorus than wheat bran, wheat middlings, cottonseed meal, or linseed meal, as they contain only 0.59 per cent. Like other seeds, soybeans lack vitamin D, and they have practically no carotene (vitamin A value). They are not rich in riboflavin, but have more riboflavin and thiamine than do the cereal grains. They are much higher than corn or oats in niacin.

For some unknown reason, feeding any large proportion of soybeans in a ration, at least for cattle, decreases the utilization of carotene or vitamin A and consequently increases the vitamin A requirement.[1] This is not of practical importance unless the ration is borderline in content of carotene or vitamin A. Soybean oil meal does not have this effect.

Soybeans should be ground for dairy cattle, but this is unnecessary for horses and sheep, and also for beef cattle if pigs follow the cattle to utilize the unchewed grain and beans in the droppings. To grind soybeans in some mills it is necessary to mix them with grain, as they tend to "gum-up" some mills, because of the high fat content. Ground soybeans are apt to turn rancid if stored long in warm weather. Because of the high fat content of soybeans, stock sometimes tire of them if fed too liberal amounts for long periods.

793. Value for non-ruminants increased by thorough cooking.—Numerous experiments have shown that the nutritive value of soybeans and of soybean oil meal for non-ruminants, such as swine and poultry, is much increased by proper cooking.[2] Such cooking greatly increases the availability and value of the protein for these animals and also destroys a substance, called the trypsin inhibitor, that depresses the growth of non-ruminants and prevents the action of the protein digestive enzymes, trypsin and erepsin.

Raw soybean protein therefore has a low value for pigs and poultry. Fortunately, properly cooked soybean oil meal or soybeans furnish protein that is equal or nearly equal in value to the protein of milk or fish meal. While thorough cooking greatly improves soybean protein for non-ruminants, too high heat or too prolonged cooking reduces the value, because it destroys or makes unavailable lysine or certain other amino acids.

The protein of soybeans is rather low in total amount of the sulfur con-

taining amino acids—methionine and cystine. However, this is ordinarily corrected by the fact that the cereal grains have a fair amount of these amino acids.

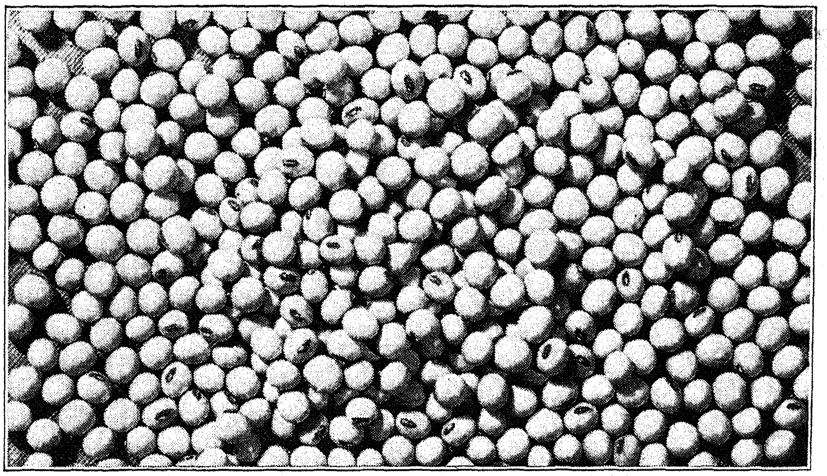
In the discussions of the use of soybeans for the various farm animals in this chapter, it is shown that, differing greatly from the results with swine and poultry, raw soybeans are a very satisfactory protein supplement for dairy cows, for beef cattle a year of age or older, for sheep, and for horses. It is pointed out later that for fattening calves, well-cooked soybean oil meal is decidedly superior to raw soybeans, while raw soybeans generally give good results as the protein supplement for older fattening cattle. (**800**)

794. Oil-milling methods.—In the processing of soybeans and other oil-rich seeds for the production of oil, three different methods are used: the hydraulic process, or so-called "old process"; the expeller process; and the solvent process.

In the hydraulic process the seed is crushed into flakes and thoroughly cooked by steam. Then the mass is formed into cakes wrapped in heavy cloth, and these are placed in hydraulic presses, where as much of the oil as possible is pressed out. The residue, which is in the form of hard cakes or slabs, is ground into meal or cracked coarsely into nut-size fragments.

In the expeller process the seed is cracked, dried, and then heated in a steam-jacketed apparatus. The oil is expressed in expellers, or screw presses, in which tremendous pressure is exerted by a worm shaft revolving in a horizontal barrel. In this process considerable heat is produced by the friction as the material passes through the expeller under the great pressure. This cooks the meal thoroughly, if the process is properly regulated. The residue, which is in flake form, is ground into meal, or may be put through machines which press it into pellets.

In the solvent process the seed is cracked, heated mildly, and rolled into thin flakes. The flakes next pass into an extracting tower where the oil is extracted by a volatile solvent. The residue is then heated and dried to remove all traces of the solvent. This solvent process removes the oil from the seed much more completely than either the hydraulic or the expeller process. For example, while expeller or hydraulic soybean oil meal



Soybeans Have Become One of Our Most Important Crops

Over 85 per cent of our acreage of soybeans is grown for seed, chiefly for the production of soybean oil and soybean oil meal.

usually has 4 to 5 per cent of fat or oil, solvent-process soybean oil meal may have less than 1 per cent.

In processing soybeans by the solvent method, the extracted soybean flakes must finally receive a special heat treatment, called "toasting," in a steam-jacketed apparatus, in order to cook them thoroughly. Otherwise, they will not be cooked enough to produce satisfactory results in feeding swine and poultry. After this, the flakes are ground to form soybean oil meal or may be pressed into pellets.

795. Soybean oil meal.—The production of soybean oil meal has increased so greatly in the United States during the past few years that it is now our most important high-protein supplement. During recent years our annual production of soybean oil meal has been well over 5,000,000 tons a year, or more than double the production of cottonseed meal.

Expeller- or hydraulic-process soybean oil meal is commonly guaranteed to contain 41 per cent protein, but sometimes the protein guarantee is 43 per cent or even higher. The 41-per cent grade contains 44.0 per cent protein, on the average, thus running well above the guarantee. Solvent-process soybean oil meal is usually sold with a guarantee of 44 per cent protein, and averages 45.7 per cent in protein content.

Expeller or hydraulic soybean oil meal of 41 per cent protein grade has an average of 4.8 per cent fat, while the solvent-process soybean oil meal has only 1.3 per cent fat. Soybean oil meal is lower in fiber than cottonseed meal or linseed meal. It ranks high in digestibility and has slightly more total digestible nutrients than cottonseed meal or linseed meal. Expeller or hydraulic soybean oil meal averages 77.9 per cent in total digestible nutrients, and although solvent-process soybean oil meal has much less fat, it is as high in total digestible nutrients.

Soybean oil meal is rather low in calcium, with an average of only 0.27 per cent for the expeller- or hydraulic-process product. It has much less phosphorus than there is in cottonseed meal or wheat bran, having an average of 0.63 per cent. Minerals are sometimes added to soybean oil meal to supply additional calcium and phosphorus, and the product is then sold under a trade name, or as mineralized soybean oil meal.

Like soybeans, soybean oil meal does not supply carotene or vitamin D. It is not rich in riboflavin, but has considerably more than corn or other grain. The niacin content is fairly high, and the thiamine content about like that of the cereal grains.

The taste of soybean oil meal indicates in a general way whether it has been cooked sufficiently to make it suitable for swine or poultry. If the soybean oil meal has a raw, "beany" taste, it has not been cooked enough for these classes of stock. Well-cooked hydraulic-process or expeller-process soybean oil meal has a pleasant nut-like taste and a light brownish or tan color. Properly-cooked solvent-process soybean oil meal may be lighter in color, and have no pronounced nut-like taste, but not a raw, "beany" taste. Chemical methods have been developed for determining whether soybean oil meal has been cooked sufficiently for feeding to poultry and swine.[3]

A few years ago certain oil mills began to use trichloroethylene instead of hexane, the usual solvent, in the solvent process. Though this solvent itself is not toxic, for an unknown reason some of the soybean oil thus produced was poisonous to cattle and certain other animals. The use of this solvent was therefore discontinued.

Because of the importance of soybean oil meal in livestock feeding, detailed information follows concerning its value and use for each class of farm animals. In general, it may be stated that soybean oil meal is one of our best protein supplements. For swine and poultry, properly cooked soybean oil meal ranks ahead of all other common protein supplements of plant origin, because of the high quality of its protein.

796. Dehulled solvent soybean oil meal.—Some solvent process soybean oil

meal is made from soybeans from which the hulls have been first removed. This dehulled solvent-extracted soybean oil meal is usually guaranteed to have 50 per cent protein. According to the definition of the Association of American Feed Control Officials, it should not have more than 3 per cent of fiber.[4]

Because of its high content of protein and low fiber content, this product is used in some high-energy mashes for chicks and broilers or in pig starters.

797. Soybean mill feed.—This is the by-product from the manufacture of soybean flour or grits and of dehulled soybean oil meal. It is composed chiefly of soybean hulls and has 29.5 per cent of fiber and only 15.7 per cent of protein. Soybean mill feed is therefore a low-grade feed, resembling hay in fiber content and value, and being far different from soybean oil meal.

The fiber guarantee of any such by-product should be noted carefully, as it will give an indication of its value in comparison with other feeds.

798. Soybeans for dairy cattle.—Ground soybeans are an excellent protein supplement for dairy cows, and in trials have been equal to linseed meal in value per ton[5] and slightly superior to cottonseed meal.[6] Even for dairy calves 2 to 3 months old at the start, ground soybeans were equal to linseed meal as the protein supplement in an Indiana test.[7]

Ground or cracked soybeans are well liked by dairy cattle when fed in such amounts as are needed to balance the ration, and are slightly laxative. In Iowa trials cracked soybeans were even satisfactory when fed as the only concentrate to dairy cows for long periods, some cows eating as much as 8.5 lbs. a day.[8] However, in Indiana experiments mixtures containing 50 per cent or more of ground soybeans were less well liked by cows than mixtures with a smaller proportion.[9]

As stated previously in this chapter, feeding to cattle a ration containing a large proportion of soybeans decreases the utilization of carotene or vitamin A. (**792**) For this reason, the vitamin A value of milk and the yellow color of butterfat may be decreased appreciably on such a ration, unless an abundance of good roughage is fed that is rich in carotene.[10] In Ohio experiments dairy cows were fed for over 3 years a concentrate mixture containing 23 per cent of ground soybeans as the only protein supplement, along with good hay and silage or else pasture.[11] The milk production equalled that on a ration containing soybean oil meal as the protein supplement, and the soybean ration did not appreciably lower the carotene or vitamin A content of the milk.

When the concentrate mixture contained 25 per cent or more of soybeans in the Indiana and Iowa trials, the fat percentage of the milk was generally increased. In 7 Indiana tests the fat test was 0.25 per cent higher on rations containing soybeans than on other rations with no soybeans. Feeding a large proportion of soybeans tends to produce soft butter, but the flavor of the milk is not injured by any ordinary amount of soybeans.[12] The effect on the character of the fat tends to decrease after a time.

799. Soybean oil meal for dairy cattle.—Soybean oil meal is one of the best protein supplements for dairy cattle, equaling linseed meal, cottonseed meal, or ground soybeans.[13] Because of the excellent quality of protein in soybean oil meal, if it is used as the chief protein supplement in a dairy calf starter, no protein supplement of animal origin is needed, such as dried skimmilk. (**1141**)

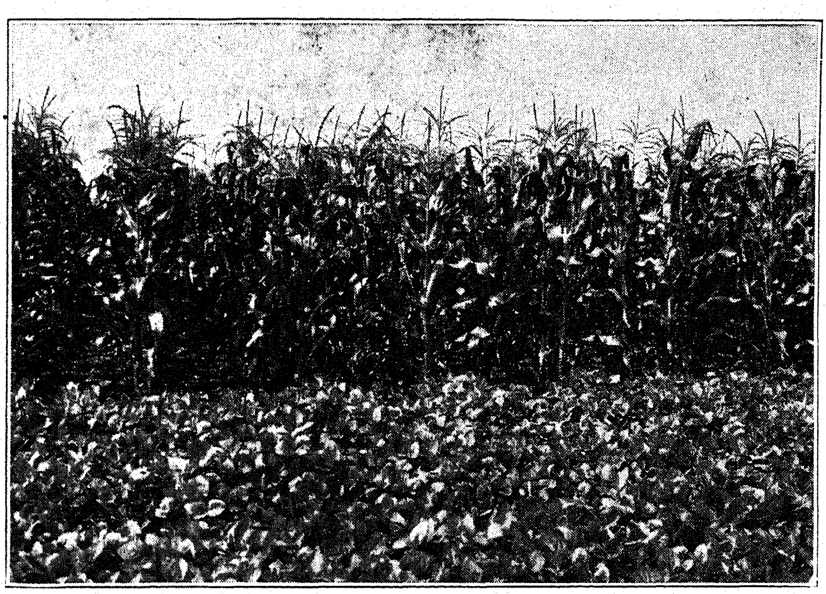
If the other feeds in the ration are low in fat, soybean oil meal made by the expeller process or the hydraulic process is preferable to solvent-process soybean oil meal, as it will help supply sufficient fat to make possible maximum milk and butterfat production. Because most of the oil has been removed from soybean oil meal, it does not affect the hardness of butter.

800. Soybeans for beef cattle.—In the soybean-growing districts soybeans are often used as the protein supplement for fattening cattle and for the breeding herd. Extensive experiments have shown that soybeans give somewhat better re-

sults as the protein supplement for fattening yearlings and older cattle than for fattening calves. This may be because calves must be fattened over a much longer period and often tire of the fat-rich soybeans during the latter part of the feeding period, or even tend to go "off feed."

In 28 experiments soybeans have been compared with soybean oil meal, cottonseed meal, or linseed meal as the only protein supplement for fattening value as the protein supplement, being worth 94 per cent as much per ton as cottonseed meal.[16]

Fattening cattle should not be fed more soybeans than are needed to balance the ration, as too large an allowance may be unduly laxative and may tend to throw the cattle "off feed." The amounts needed to balance various rations are shown in Appendix Table VII. Soybeans need not be ground for beef cattle which are followed by pigs.



SOYBEANS THRIVE WHERE CORN CAN BE GROWN

Soybeans are drouth resistant, are adapted to a wide range of soils, stand considerable frost, and do well on soil too sour for alfalfa.

two-year-old or yearling cattle.[14] The cattle fed soybeans as the supplement have gained as fast or nearly as fast as those fed the other supplements. In these many trials soybeans were worth slightly more per ton than soybean oil meal or cottonseed meal, and as much as linseed meal.

For fattening calves soybeans have been a decidedly less satisfactory protein supplement than soybean oil meal or linseed meal in 7 experiments, and worth considerably less per ton.[15] In 11 trials with fattening calves soybeans more nearly approached cottonseed meal in

801. Soybean oil meal for beef cattle.—Soybean oil meal is one of the best protein supplements for beef cattle, being excellent for fattening cattle and for the breeding herd. Because soybean oil meal is not high in fat, fattening cattle do not show the tendency to tire of it during a long feeding period, which sometimes occurs with soybeans. Also, soybean oil meal is only slightly laxative and does not produce scours when fed in considerably larger amounts than are needed to balance the ration.

In 20 experiments fattening cattle made equal gains when fed soybean oil

meal in comparison with cottonseed meal as the supplement.[17] The cattle fed soybean oil meal required a little less feed per 100 lbs. gain and sold for a few cents more per hundredweight, on the average. In these experiments the average net return would have been equal, if soybean oil meal had cost 28 per cent more per ton than cottonseed meal.

In Nebraska tests when a mineral mixture was fed to supply additional phosphorus, soybean oil meal was about equal to cottonseed meal as the protein supplement for beef calves wintered on prairie hay.[18] On the other hand, cottonseed meal produced slightly better results when the mineral mixture was not fed.

Soybean oil meal has not proven equal to linseed meal as the only protein supplement for fattening cattle. In 11 experiments cattle fed soybean oil meal as the supplement gained 0.1 lb. a day less than others fed linseed meal, required a little more feed per 100 lbs. gain, and sold for 13 cents less per hundredweight.[19] Taking all these seemingly small differences into consideration, it would have been necessary to buy soybean oil meal at only 67 per cent of the price of linseed meal to make an equal net return over cost of feed and cattle.

A small difference in the selling price of fat cattle makes considerable difference in the value of a protein supplement, because it applies to the entire weight of the cattle when marketed, and this difference in sale value must be charged against the rather small amount of supplement fed during the fattening period.

Solvent-process soybean oil meal has been fully equal to expeller-process or hydraulic-process soybean oil meal in feeding value in 8 tests with fattening cattle and 3 trials with calves being wintered.[20] The solvent-process product may sometimes be a trifle less palatable, however.

802. Soybeans and soybean oil meal for sheep.—Both soybeans and soybean oil meal are excellent protein supplements for sheep feeding. Experiments have shown that they are usually equal to linseed meal or cottonseed meal in value per ton.[21] There seems to be little choice between soybeans and soybean oil meal for feeding sheep, since the results with these two supplements have been practically the same, on the average, in 10 trials with fattening lambs.[22] It does not generally pay to grind soybeans for sheep.

If not much higher in price per ton than corn, soybean oil meal can be used economically as the only concentrate for fattening lambs fed roughage low in protein.[23]

803. Soybeans and soybean oil meal for horses and mules.—Both ground soybeans and soybean oil meal are very satisfactory protein supplements for horses and mules. Not more than 1 lb. per head daily of either of these feeds is needed to balance any usual ration for horses and mules. Soybeans should not form over one-third the concentrate mixture, else they may cause digestive trouble, owing to their heavy nature. Farmers have reported that feeding a small amount of soybeans to horses in the spring seems to have the same effect as linseed meal, in making their hair smooth and sleek.[24]

804. Soybeans for swine.—Soybeans have very definite limitations for swine feeding. It is therefore wise for soybean growers to exchange soybeans for soybean oil meal to feed to swine, unless the price of soybean oil meal is considerably higher.

First of all, if growing and fattening pigs are fed soybeans as the only protein supplement to grain and the ration contains more than about 10 per cent of soybeans, the pork is apt to be soft.[25] If pigs in dry lot weigh at least 125 lbs. and pigs on pasture at least 70 lbs. before soybean feeding is begun, and if the amount of soybeans is no greater than is needed to balance the ration, satisfactory carcasses are usually produced.

The second limitation is that for pigs not on good pasture raw soybeans are decidedly inferior in nutritive value to soybean oil meal or to well-cooked

soybeans.[26] Cooking soybeans involves considerable labor and expense.

Except for the softening effect on the carcass, raw soybeans, fed as the only protein supplement, give better results with well-grown pigs than with young pigs, and are more satisfactory for pigs on pasture than for those in dry lot. For example, in 33 experiments on first-rate pasture, pigs fed raw soybeans and minerals as the supplements to corn gained 1.43 lbs. a day, in comparison with 1.54 lbs. for others fed soybean oil meal or tankage instead of soybeans. In these experiments, not considering the difference in rate of gain and the danger of producing soft pork on the soybean ration, 100 lbs. of soybeans were equal to 87 lbs. soybean oil meal plus 24 lbs. corn,[27] or to 60 lbs. of tankage plus 37 lbs. corn.[28]

Raw soybeans are decidedly inferior to soybean oil meal or cooked soybeans for pregnant sows or those nursing litters.[29]

Soybeans that have been thoroughly roasted or otherwise cooked produce satisfactory gains when fed with corn and a calcium and phosphorus supplement, even to pigs not on pasture.[30] However, cooking the soybeans does not at all prevent the softening effect on the carcass. Also, roasted soybeans are so palatable to pigs that, when the soybeans are self-fed, the pigs will eat much greater amounts than needed to balance the ration. If a mixture of shelled corn and the proper proportion of roasted soybeans is fed, the pigs will sort out the soybeans from the corn. It is therefore necessary to hand-feed the roasted soybeans, or to self-feed a mixture of suitable amounts of ground corn and ground soybeans.

In using soybeans as the protein supplement for swine, it is important to provide a mineral mixture supplying both calcium and phosphorus, even for pigs on good pasture. In the case of swine not on pasture, legume hay should be included in the ration, if possible, as an insurance against lack of vitamins. There is no need of grinding soybeans for swine.

Missouri tests show that feeding pigs a ration containing 25 per cent or more of soybeans increases the tendency of the pork to become rancid on storage in a freezer.[31]

When pigs are used to hog down a field of ripe soybeans, they make satisfactory gains if supplied with a mineral mixture and fed a limited amount of corn in addition. However, the carcasses will be decidedly soft.

805. Soybean oil meal for swine.—Soybean oil meal that has been properly cooked in the manufacturing process is the best of all common protein supplements of plant origin for swine feeding. For pigs and other swine on good pasture it gives excellent results when used as the only protein supplement, if a mineral supplement is provided to supply additional calcium and phosphorus.

In each of 19 trials one lot of pigs, averaging 64 lbs. in weight at the start, was full-fed corn on good pasture, with soybean oil meal and with minerals to supply additional calcium and phosphorus, while another lot was fed tankage or meat scrap as the supplement.[32] The pigs fed soybean oil meal equalled those fed tankage or meat scrap in rate of gain, but they required a trifle more feed per 100 lbs. gain. On the average, 100 lbs. of soybean oil meal equalled 43 lbs. tankage plus 44 lbs. corn, but minus 3 lbs. mineral mixture, in feeding value.

Soybean oil meal is also very satisfactory as the only high-protein supplement to grain for well-grown pigs not on pasture, if legume hay is included in the ration, as well as a calcium and phosphorus supplement. However, the experiments reviewed in Chapter XXXIV have shown that young pigs in dry lot, placed at weaning time on such a ration as corn, soybean oil meal, and minerals, may not thrive even when 5 per cent of good-quality alfalfa hay is included in the ration. Some may become runts or be unable to walk normally. Similarly, if brood sows are raised in dry lot on such rations and continued on them during pregnancy, many of the pigs may be weak at birth or the sows may be un-

able to provide enough milk for them. Poor results sometimes occur even on rations containing protein supplements of animal origin, but are more frequent when no meat scrap, tankage or fish meal is fed. These troubles are due to deficiencies of certain vitamins.

Such troubles may be prevented by raising the sows on good pasture and by including 15 per cent of good alfalfa hay or other legume hay in their winter rations. Pigs will not generally show these deficiencies if they are well started on good pasture before they are placed in dry lot, and are then fed such rations only after they have reached a weight of 60 to 75 lbs.

Soybean oil meal has a great advantage over soybeans as a supplement for fattening pigs, because it does not produce soft pork when fed in any ordinary amount. Properly cooked soybean oil meal is liked so well by pigs that if it is self-fed, free-choice, as the supplement to grain, they will often eat much more of the soybean oil meal than they need to balance their ration. To prevent this, the soybean oil meal can be hand-fed in the proper amount, or some less palatable feed, such as ground alfalfa hay, can be mixed with it.

Particularly good results are secured when soybean oil meal is used in combination with the protein supplements of animal origin, as in a trio-type mixture. Various desirable combinations are discussed in Chapter XXXIV.

Well-cooked soybean oil meal is of approximately the same value for swine, no matter whether made by the expeller process, the solvent process, or the hydraulic process. In 12 experiments toasted solvent-process soybean oil meal has been compared with expeller-process soybean oil meal as the supplement to corn for pigs on pasture or in dry lot. A mineral mixture was fed in addition and alfalfa hay was usually included in the rations for the dry-lot pigs.[33] On the average, the pigs fed solvent-process soybean oil meal gained 1.23 lbs. and those fed the expeller-process product just a trifle more, 1.25 lbs. Each 100 lbs. of the solvent-process soybean oil meal equalled 108 lbs. of expeller-process soybean oil meal minus 19 lbs. of corn in feeding value.

806. Soybean oil meal and soybeans for poultry.—Among common feeds, soybean oil meal which has been thoroughly cooked in the manufacturing process is the best substitute for protein supplements of animal origin in poultry feeding. Raw soybeans or even cooked soybeans are much less satisfactory than soybean oil meal and have a considerably lower value. Soybeans should therefore be used for poultry only when better protein supplements are not readily available.

Numerous experiments have been conducted to find the extent to which soybean oil meal can be used satisfactorily in poultry rations to replace such supplements as fish meal, meat scrap, and milk by-products.[34] These investigations have shown that in using soybean oil meal as the chief protein supplement it is especially important to correct the deficiencies of calcium and riboflavin. Also, a phosphorus supplement should be added to the ration, if necessary, as soybean oil meal is only fair in phosphorus content. If the ration is thus properly supplemented, soybean oil meal gives excellent results when used to replace at least one-half of the animal protein needed to balance rations for chicks, growing pullets, or laying hens.

When there is a shortage of animal-protein supplements, as occurred in World War II, satisfactory results are generally secured when soybean oil meal replaces a considerably larger part of the feeds of animal origin. If great care is taken to supply proper amounts of calcium, phosphorus, riboflavin, and other B-complex vitamins, reasonably good egg production and growth of chicks can be secured when soybean oil meal replaces all the fish meal, meat scrap, or tankage in usual rations. However, for rapid growth and fattening of broilers and for high hatchability of eggs, a minimum amount of such animal feeds should be included in the ration. Too large a proportion of soybean oil meal in the start-

ing mash for chicks may cause trouble from "pasting up," in which the feces stick to the down.

In most tests, solvent-process soybean oil meal that has been properly cooked has been equal to expeller-process or hydraulic-process soybean oil meal that has also been well cooked.[35] Soybean oil meals of the same type may vary in value, depending on the care taken by the manufacturer to control the temperature to which the soybean oil meal is heated. Sufficient cooking is essential, but overcooking is detrimental.

If ground raw soybeans are used for poultry, they had best be used to replace not more than one-third of the animal-protein supplements.[36] Soybeans give better results when fed to poultry on good pasture than for birds in confinement. Thorough cooking of soybeans by roasting or boiling increases their value for poultry, but cooked soybeans are not so satisfactory as soybean oil meal. Sprouting soybeans increased their value in a New Jersey test but did not improve them appreciably in a Maryland trial.[37] In any event, sprouting requires considerable labor and trouble.

Colorado studies show that raw soybeans may have a tendency to produce goiter in chicks, unless iodine is added to the ration.[38]

II. Cottonseed and Cottonseed By-products

807. Importance of the cotton crop.—Cotton (*Gossypium hirsutum*) ranks next to corn and wheat in value in the United States, and is the most important southern crop. Cotton is grown primarily for the fiber, but cottonseed meal and cake, secured in the production of oil from cottonseed, are among our most important feeds. Also, cottonseed hulls are one of the most common roughages in the South.

During recent years about 2,400,000 tons of cottonseed meal and cake and 1,300,000 tons of cottonseed hulls have been produced a year in the United States. From each ton of cottonseed there are secured approximately the following: Cottonseed cake or meal, 954 lbs.; crude oil, 303 lbs.; hulls, 514 lbs.; and linters, or short fiber, 110 lbs.; with dirt and loss in manufacturing amounting to 119 lbs.[39]

808. Manufacture of cottonseed meal and cake.—At the oil mills, after the cottonseed has been cleaned and more or less of the short lint covering the seed has been removed, the leathery hulls of the seed are cut by machines, so the kernels can drop out. The kernels are separated more or less completely from the hulls by shakers and beaters, containing metal screens. After the kernels are crushed, as much of the oil as possible is removed by one of the oil-milling methods. (794) The residue after most of the oil is removed is cottonseed meal or cake.

Until recently, the hydraulic method was commonly used in processing cottonseed, but now the expeller method is used extensively, and some mills use the solvent method or a combination of preliminary treatment in expellers, or screw presses, followed by solvent extraction (called the prepress solvent method).

The large cakes of cottonseed cake produced in the hydraulic method are ground to form cottonseed meal, or broken into pieces of pea or nut size for sale as cottonseed cake. Some cottonseed meal is put through pelleting machines to produce pellets or cubes of various sizes. For feeding outdoors, especially for use on the western ranges, cottonseed cake or pellets are preferred to cottonseed meal, as they are not scattered by the wind. In the eastern and central states and for feeding to dairy cattle cottonseed meal is generally used. Since most of the product is fed in this country as cottonseed meal, and also since the meal and cake have the same general value, the term cottonseed meal will be commonly used in this volume in referring to both cottonseed meal and cottonseed cake.

The following sizes of cottonseed cake are made in this country: *Nut-size cake,* consisting of pieces from three-fourths to 1.5 inches in diameter; *sheep-size cake,* from five-eights to seven-eights inch; *pea-size cake,* from three-eights to

five-eights inch; and *pebble-size cake,* under three-eights inch in diameter.

809. Grades of cottonseed meal or cake.—Because cottonseed meal and cake are used chiefly as protein supplements, they are graded and sold on the basis of the guaranteed protein content, in addition to the general quality. To conform to the official definitions of the Association of American Feed Control Officials, cottonseed meal or cake must contain at least 36 per cent of protein and must be composed principally of the kernel, with only such portion of the hull as is necessary in the manufacture of oil.[4] If the product has less than 36 per cent of protein, it must be sold as cottonseed feed.

Cottonseed meal is classed either as *prime quality* or *off quality.* According to the official definition, *cottonseed meal, prime quality* must be finely ground, not necessarily bolted, be free from excessive lint, must not have a sour, musty, or burnt odor, and must contain not less than 36 per cent of protein. It must be designated and sold according to its protein content. For example, prime-quality cottonseed meal guaranteed to contain 41 per cent protein must be designated as "41 per cent protein cottonseed meal, prime quality." Cottonseed meal that is not high grade in odor or texture is designated as "off quality."

Because of the variation in composition, cottonseed meal or cake should always be purchased on definite guarantees, not only of protein content but also of fat and fiber. The grades with lower protein content not only supply less protein but are also higher in fiber, because the hulls are usually removed less completely. Such meal therefore furnishes less total digestible nutrients than that which has 41 per cent or more of protein.

The cottonseed raised in certain sections of the Southwest, especially in Texas, is higher in protein than the seed produced in other cotton-growing districts. For this reason, 41 per cent protein cottonseed meal from such seed usually contains slightly more hulls and is therefore a little higher in fiber and

PICKING A CROP OF COTTON

Cotton is by far the most important crop in the southern states. The cottonseed meal and cake produced in the processing of cottonseed for oil rank next to soybean oil meal in importance among the high-protein supplements used for stock feeding. (From Ward, Educational Service, National Cottonseed Products Association.)

lower in feeding value than cottonseed meal containing 41 per cent protein from districts where cottonseed is lower in protein.

810. Composition and nutritive properties.—Cottonseed meal of the usual grades contains 41 per cent protein or more, thus having nearly as much as soybean oil meal. It supplies protein of satisfactory quality for cattle, sheep, or horses, when used as the only or the chief protein supplement. However, cottonseed meal does not furnish protein of high quality for swine or poultry, chiefly because it is rather low in lysine. For them, it should therefore be used in combination with such supplements as tankage, meat scrap, fish meal, milk by-products, or soybean oil meal. Such combinations will not only provide protein of better quality, but will also prevent injury from gossypol, which is discussed later.

In Oklahoma comparisons of cottonseed meals made by the solvent process and the hydraulic process, there were no appreciable differences in digestibility or in the value of the protein for beef steers or lambs.[40]

Most of the cottonseed meal produced by the hydraulic or expeller methods has 5 per cent fat or slightly more. The fat content was somewhat higher before modifications had been made in these methods which made possible more complete removal of the fat, or oil. Solvent-process cottonseed meal is much lower in fat.

High-grade cottonseed meal supplies slightly less total digestible nutrients than does linseed meal. The solvent-process meal is somewhat lower than the expeller-process or hydraulic-process meal, because of the lower fat content.

Cottonseed meal is one of the richest feeds in phosphorus, containing about 1.0 per cent or more. In contrast to the high phosphorus content, it has only about 0.2 per cent calcium. Like other seed products, cottonseed meal lacks vitamin D, and it also has little or no carotene (vitamin A value). These lacks can readily be made good by including in the ration a sufficient amount of well-cured legume hay or mixed hay high in legumes. If grass hay, such as timothy or prairie hay, is of excellent quality, it will supply these necessary nutritive factors, except that it may not furnish enough calcium, unless grown on soil rich in lime. Cottonseed meal has a fair content of the B-complex vitamins.

Cottonseed meal tends to produce milk fat of a high melting point and hard body fat. It thus helps to overcome the tendency of peanuts and soybeans to produce soft pork. Cottonseed meal may be slightly constipating in effect, but not noticeably so when it is fed with such feeds as legume hay or silage. This effect may be advantageous when considerable amounts of very laxative feeds are used, such as beet molasses or sugar beet tops.

811. Cottonseed meal as a feed.—Cottonseed meal is one of the best protein supplements for dairy cows, beef cattle, and sheep. For swine and poultry the ordinary kinds of cottonseed meal should be fed in strictly limited amounts, because of the danger of injury from a substance called gossypol which ordinary cottonseed meal contains.

Raw cottonseed contains appreciable amounts of gossypol, the amount varying considerably with the climate and the soil. Gossypol is poisonous to certain kinds of animals if consumed in sufficient amounts. Fortunately, in the heating that occurs in the process of oil manufacture much of the gossypol is changed into a substance (called d-gossypol, or bound gossypol) which is much less poisonous.

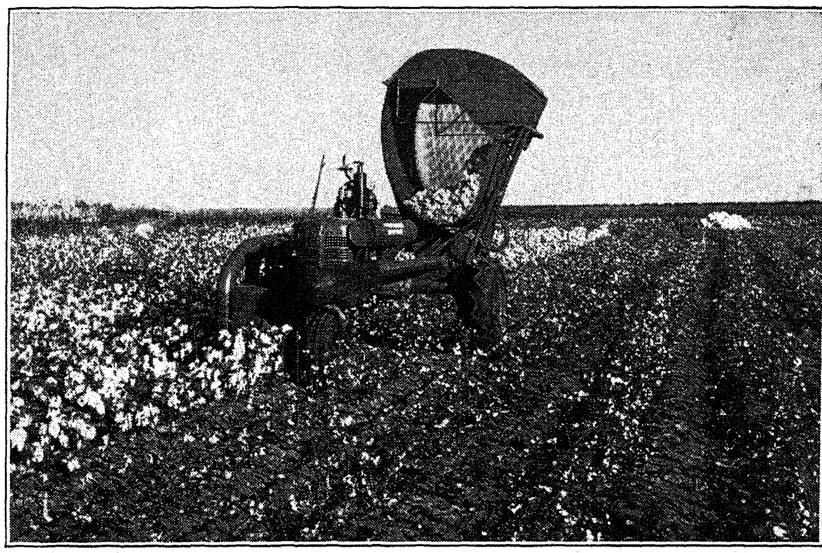
Extensive experiments have proved that cattle over 3 or 4 months of age may safely be fed large amounts of ordinary cottonseed meal continuously for long periods, if care is taken to provide plenty of high-quality hay or good pasturage.[41] Such roughage makes good the lack of carotene and other possible deficiencies in the cottonseed meal and the other concentrates usually fed.

These investigations have proved that in the case of cattle these deficiencies are the primary cause of the so-called "cottonseed-meal poisoning" which often occurs when stock are

heavily fed on cottonseed meal and roughage low in vitamins and calcium. Cattle are not affected by the amount of gossypol usually present in cottonseed meal, or even in cottonseed. Thus, in Oklahoma experiments dairy cows have not been injured when they have been fed as much as 10 lbs. of cottonseed meal per head daily for 3 years with good roughage, but without any pasture.[42]

ing. Sheep may be fed as much ordinary cottonseed meal as is needed to balance their rations, but should not be fed large amounts continuously for long periods. However, as is shown later, lambs have been fattened satisfactorily for the usual length of time on cottonseed meal as the only concentrate, fed with plenty of legume hay. (**816**)

Swine, poultry, and young calves are injured by an appreciable amount of free gossypol in the ration. Horses and mules must also be fed ordinary cottonseed meal with caution. The following articles state the proportions of ordinary cottonseed meal that can be fed safely to these classes of stock.



A MECHANICAL COTTON PICKER

Cotton pickers have been recently developed which greatly reduce the expense of harvesting the crop. (From Ward, Educational Service, National Cottonseed Products Association.)

Symptoms similar to the so-called "cottonseed-meal poisoning" were produced in some of these experiments when cattle were fed rations low in carotene but which included no cottonseed products whatsoever. Provided the injury on such a ration as cottonseed meal and hulls had not progressed too far, the animals could be cured rather rapidly by feeding cod-liver oil, good legume hay, or fresh green forage.

For calves under 3 to 4 months of age it is best not to use more than about 20 per cent of ordinary cottonseed meal in the concentrate mixture. A larger proportion is apt to cause gossypol poisoning.

The investigations which have proved that with good roughage cottonseed meal can be safely fed to dairy cows and other cattle, except young calves, in large amounts and even as the only concentrate, are of especial importance in the southern states. There cottonseed meal is frequently the cheapest source not only of protein but also of digestible nutrients. Under these conditions it is

often economical to feed cottonseed meal as the only concentrate to dairy cows and beef cattle, or at least in considerably larger amounts than are needed to balance the ration in protein content.

812. Low-gossypol cottonseed meal.—Cottonseed meal produced by the usual methods, no matter whether hydraulic, expeller, or solvent, varies widely in content of free gossypol. In North Carolina studies, for example; 114 samples of cottonseed meal tested had an average of 0.093 per cent, with the wide range of 0.030 to 0.208 per cent.[43] To be used with safety in any large proportion in swine rations, cottonseed meal should not have more than 0.04 per cent free gossypol, and in poultry rations not more than 0.02 per cent.

Considerable research has therefore been conducted, especially by the Southern Regional Laboratory of the United States Department of Agriculture, to develop practical methods of processing by which cottonseed meal can be made that will uniformly have so little free gossypol that it can be safely fed in large amounts to swine and poultry.[44]

In some of the experiments thus far conducted, low-gossypol cottonseed meal has been satisfactory and has produced no injury when fed as the only protein supplement to pigs.[45] However, in other trials the results have not been good.[46]

By treating ordinary cottonseed meal several hours before feeding it with a solution containing 3.4 lbs. of ferrous sulfate per 100 lbs. of cottonseed meal, it was made safe for pigs in Ohio experiments.[47] This treatment destroys the free gossypol or changes it into the inactive form. In Mississippi tests merely mixing 0.3 lb. of dry ferrous sulfate with each 100 lbs. of a feed mixture high in cottonseed meal made it safe for pigs.[48]

813. Cottonseed meal for dairy cattle.—Cottonseed meal is one of the most widely-used protein supplements for dairy cows, because it is very rich in protein, the protein is of satisfactory quality for ruminants, and the feed is well liked by cattle. Cottonseed meal is usually the cheapest source of protein in the southern states, and is often one of the most economical protein supplements in the North.

The experiments reviewed previously have shown that no definitely poisonous effects are produced even when cottonseed meal is fed as the only concentrate to cows for long periods, provided the roughage is of first-class quality. However, it is not wise to feed such a ration unless necessary. Instead, cottonseed meal should ordinarily be combined with grain and other feeds in the usual type of dairy concentrate mixture.

In Oklahoma and South Carolina experiments the feeding of cottonseed meal as the only concentrate for long periods lowered the fat content of the milk and also the solids-not-fat content.[49] Also, in the South Carolina trials such feeding of cottonseed meal for a long time seemed to have a detrimental effect on the health and reproduction of high-producing cows.

If cottonseed meal or cottonseed form too large a part of the concentrates fed cows, the butter is apt to be hard, sticky, and tallowy.[50] In addition, an abnormally long time is required for churning. This effect is reduced when the cows have silage or pasture. Contrary to the opinion sometimes expressed, heavy feeding of cottonseed meal has not increased the tendency to mastitis in the cows, or made the trouble more severe in the case of cows affected with the disease.

While cottonseed meal is not quite so palatable as linseed meal, it is well liked by cattle. Since it does not have the conditioning effect of linseed meal, many dairymen prefer to use both of these feeds as sources of protein in a concentrate mixture, rather than to use cottonseed meal as the only supplement. Wheat bran and soybean oil meal are also excellent feeds to use along with cottonseed meal. Even though the cost may be increased by furnishing this greater variety, the practice may be preferable, especially for cows of high productive capacity.

In Indiana trials cottonseed meal, linseed meal, and gluten feed were compared as supplements to a ration of

ground corn, corn silage, and legume hay.[51] The amount of each supplement was adjusted so that all rations furnished the same amount of protein. Thus fed, the production on the cottonseed-meal ration was fully as high as on the others. In a Virginia trial cottonseed meal for dairy cows was worth about 90 per cent as much as corn gluten meal, which is appreciably higher in digestible protein and in total digestible nutrients.[52]

When cottonseed meal is cheaper per ton than grain, as is sometimes the case in the South, it is economical to include more of it in the concentrate mixture than is needed to balance the ration. When the proportion of cottonseed meal in the concentrate mixture was increased from 11 per cent to about 50 per cent in Oklahoma experiments, the milk production was slightly higher.[53] Each 100 lbs. of additional cottonseed meal was worth 10 per cent more than the mixture of corn, oats, and wheat bran which it partly replaced.

Ordinary cottonseed meal may be used satisfactorily in a concentrate mixture for calves, if the mixture does not contain more than about 20 per cent of cottonseed meal and if the calves are supplied with good roughage, high in carotene. For example, in South Carolina experiments good results were secured with a calf meal consisting of 20 lbs. cottonseed meal, 39 lbs. ground yellow corn, 40 lbs. ground oats, and 1 lb. salt.[54] After calves are 3 to 4 months old, they may be fed larger proportions of cottonseed meal with safety. As the chief protein supplement in a calf starter, cottonseed meal is less satisfactory than soybean oil meal, because the quality of the protein is not so good.[55]

Too large a proportion of cottonseed meal of the usual kinds, even 40 per cent, in a mixture for calves is dangerous.[56] Holstein calves seem to be more susceptible to cottonseed meal toxicity than Jerseys.

In a Mississippi experiment a ration of cottonseed meal as the only concentrate with hay and silage was not satisfactory for dairy bulls, while the results were good on a mixture of one-third each of cottonseed meal, ground corn, and ground oats.[57]

814. Cottonseed meal or cake for beef cattle.—In this country cottonseed meal and cake are used extensively for beef cattle. They are very satisfactory supplements and are so rich in protein that only relatively small amounts are needed to balance rations low in this nutrient. In addition, cottonseed meal and cake are so high in phosphorus that they serve as phosphorus supplements, as well as protein supplements.

It is shown in Chapter XXVIII that when the proper amount of a high-protein supplement like cottonseed meal is added to a ration deficient in protein for fattening cattle, each 100 lbs. of the supplement will usually be equal in value to 250 to 300 lbs. of corn or other grain. Not only will less feed be required for each 100 lbs. gain on the properly balanced ration, but also the cattle will reach a better finish and consequently sell for a higher price.

The experiments summarized elsewhere in this chapter show that when cottonseed meal or cake is used as the only protein supplement to balance the usual rations for fattening cattle, it is worth decidedly less per ton than linseed oil meal or soybean oil meal. (**831, 801**) However, when cottonseed meal is combined with linseed meal, the combination is worth about as much as linseed meal.

When added to a ration that is somewhat too laxative, cottonseed meal or cake is superior to linseed meal as the supplement for fattening cattle, because it tends to counteract the laxative effect. For example, in Colorado tests cottonseed cake was a better supplement than linseed meal for fattening cattle which were fed liberal amounts of wet beet pulp and also beet molasses.[58]

Cottonseed cake and pellets are widely used as the protein supplement for beef cows or growing cattle being wintered on the range, 1 lb. per head daily being a common allowance. For this purpose cottonseed cake or meal has been about equal to soybean oil meal or linseed meal in Kansas and Mississippi

experiments, and somewhat lower in value in Oklahoma trials.[59]

To avoid wastage, cottonseed cake or pellets are generally used instead of cottonseed meal for beef cattle under ranch conditions and for fattening cattle in western feed lots where little or no shelter is provided. In feeding cottonseed cake as a winter supplement for range cattle, a common practice is to distribute it on the ground, the larger sizes of cake being preferred. Sometimes a mixture of cottonseed meal and salt is self-fed, the proportion of salt being adjusted so that the cattle will eat the desired amount of meal. (**1170**) It makes little difference whether cottonseed cake or meal is used when it is fed under shelter and in feed bunks.

In several experiments cottonseed cake has been compared with alfalfa hay as a supplement for calves that were being wintered on non-legume roughages. In these tests each 100 lbs. of cottonseed cake, fed at the rate of 1 lb. per calf daily, has equalled about 300 lbs. of alfalfa hay in actual feeding value. Where cottonseed cake or meal has been compared with grain as a supplement to non-legume roughage for wintering cattle in similar experiments, it has required about 2 lbs. of grain to take the place of 1 lb. of cottonseed meal.

In 2 Oklahoma and 3 Texas trials with fattening cattle solvent-process cottonseed meal as the protein supplement produced slightly less rapid gain than hydraulic-process cottonseed meal.[60] Somewhat more feed was required per 100 lbs. gain with the solvent cottonseed meal, and it was worth decidedly less per ton than the hyraulic meal.

815. Feeding large amounts of cottonseed meal.—In the southern states cottonseed meal is often cheaper per ton than corn or other grain, and it is then frequently fed to fattening cattle as the only or the chief concentrate. If care is taken to provide an ample supply of carotene and of calcium, cattle can ordinarily be fed large amounts of cottonseed meal with good results, and without any injury whatsoever. Well-cured hay, good silage, or green pasture all supply liberal amounts of carotene. Unless a reasonable amount of legume forage is fed, a calcium supplement should be supplied.

If cottonseed meal is lower than grain in price per ton, it is important to know what its relative value is in comparison with corn or other grain, when more is fed than is required to balance the ration. Several experiments have shown conclusively that the gains of fattening cattle are generally not increased by feeding a larger proportion of cottonseed meal than is needed. Also, when cottonseed meal is fed as a grain substitute, each 100 lbs. of cottonseed meal fed beyond the amount needed to balance the ration is worth only about as much as 96 lbs. of corn,[61] or a trifle less than 100 lbs. of ground barley.[62]

If somewhat more cottonseed meal is added to a ration that does not contain quite enough of the meal to balance the ration fully, its value will be higher than that of grain. For example, in 2 Texas comparisons calves fed 3.6 lbs. per head daily of cottonseed meal, with milo grain and low-protein roughage, gained slightly more than others fed 1.6 lbs. cottonseed meal.[63] The additional amount of cottonseed meal was worth considerably more than milo, pound for pound.

In some experiments in which different amounts of cottonseed meal have been fed, the gain has been much more rapid on the larger allowances. However, in these trials the total amount of concentrates (grain plus cottonseed meal) has been greater. The increase in the rate of gain was thus due to the larger amount of total concentrates, and not to any superiority of cottonseed meal over grain, when fed merely as a grain substitute.

Since legume hay is rich in protein, it is best to use it in combination with such roughage as corn or sorghum silage or fodder or else cottonseed hulls for fattening cattle that are fed protein-rich cottonseed meal as the only or the chief concentrate. In Texas trials very poor results were secured when peanut or alfalfa hay was fed to steers with 5 lbs. of cottonseed meal per head daily.[64] When

shelled corn was substituted for a part of the cottonseed meal or when prairie hay was fed in place of the legume hay, the gains became normal.

Cottonseed meal or cake should not ordinarily be used as the only concentrate for fattening calves, as they then tend to grow rather than fatten.[65] The results are better when they are fed not more than 8 to 10 lbs. of cottonseed meal per head daily, along with some grain.

Years ago the most common ration for fattening cattle in the South was cottonseed meal and cottonseed hulls, without any hay or silage. On this restricted ration cattle will usually make satisfactory gains for 2 or 3 months, but later they are apt to become unthrifty and suffer from the effects of the vitamin deficiency. This can be prevented by adding to the ration enough well-cured hay or good silage.

Therefore, for breeding cattle or for fattening cattle which are to be fed for several months, it is important to feed carotene-rich roughage along with a ration of cottonseed meal and hulls. Even in the case of cattle that are to be fattened for only 100 days or less, better results will usually be secured if a limited amount of good hay or silage is supplied.

816. Cottonseed meal or cake for sheep.—Cottonseed meal or cake is an excellent protein supplement for fattening lambs or for breeding sheep. Differing somewhat from the results with fattening cattle, cottonseed meal is practically equal to linseed meal or soybean oil meal for fattening lambs, if considerable legume hay is fed and if no more of the supplement is used than is actually needed. Since high-grade cottonseed meal is richer than linseed meal in protein, slightly less of it is required to balance a ration.

In 19 experiments cottonseed meal has been directly compared with linseed meal as the protein supplement to rations of corn grain and legume hay, with corn silage in addition in some cases.[66] The lambs fed cottonseed meal have made about as rapid gains as those fed linseed meal and there has been no appreciable difference in the amounts of feed required per 100 lbs. gain or in the selling price of the lambs. On the other hand, in 6 comparisons in which only a trifle of legume hay was fed with corn silage and oat straw as the chief roughages, cottonseed meal was worth about 88 per cent as much per ton as linseed meal.[67]

Cottonseed meal is excellent as the only protein supplement for wintering breeding ewes. In Oklahoma tests the results were satisfactory when as much as 0.5 lb. per head daily was fed with prairie or alfalfa hay.[68]

In the southern and southwestern states cottonseed meal, when low in price, is sometimes fed as the only concentrate to fattening lambs. If more cottonseed meal is fed than is needed to balance the ration, the additional amount is usually worth no more per pound than corn or other grains, and may be worth even less. In 4 Texas trials fattening lambs fed 1.2 lbs. cottonseed cake a day, with alfalfa hay for roughage, gained slightly less than others fed sorghum grain, alfalfa hay, and 0.16 lb. cottonseed cake.[69] Each 100 lbs. of additional cottonseed cake fed the first lots was worth only about 90 per cent as much as sorghum grain. The results were similar in Oklahoma trials in which fattening lambs were fed a large amount of cottonseed meal and a little corn, with alfalfa hay for roughage.[70]

When sheep are fed large amounts of cottonseed meal, there is danger of "cottonseed meal injury," unless they get plenty of good legume hay or other roughage rich in carotene. For example, lambs can be successfully fed cottonseed meal as the only concentrate with alfalfa hay for 90 to 100 days, but when cottonseed meal has been fed with cottonseed hulls as the only roughage for the entire fattening period, some lambs have died.[71]

817. Cottonseed meal for horses and mules.—Cottonseed meal is often used, especially in the South, as the protein supplement for horses and mules, and gives satisfactory results if not more than about 1 to 1.5 lbs. are fed daily per

1,000 lbs. live weight.[72] Sometimes even larger amounts have been fed successfully.[73]

When cottonseed meal is added to a ration low in protein, it is worth considerably more per pound than corn or other grain. Such balancing of the ration improves the condition and appearance of the horses or mules. Using cottonseed meal as a large part of the concentrates is not safe, as it may cause serious digestive disturbances because of its heavy nature. Also, it may be poisonous when too much is fed. Only good-quality cottonseed meal should be fed to horses or mules.

If more than 1.0 to 1.5 lbs. daily of cottonseed meal are fed, it is a good plan to mix it with a bulky feed, such as oats, bran, or corn-and-cob meal. It is best to feed not over one-fourth pound per head daily at first and then gradually to increase the allowance as the horses become accustomed to it.

818. Cottonseed meal for swine.—It is not safe to use ordinary cottonseed meal as the only protein supplement in swine feeding, because of the danger of gossypol poisoning. However, excellent results are secured when the amount of cottonseed meal is strictly limited and it is combined with supplements which supply protein of better quality. When pigs are fed soybeans or peanuts, the fact that cottonseed meal tends to make hard fat may be of distinct advantage in counteracting the effect of feeds, such as soybeans and peanuts, which produce soft pork.

Extensive investigations, especially experiments at the Ohio and Texas Stations, have shown that swine rations should not contain more than about 9 to 10 per cent of cottonseed meal and that they should provide protein of good quality and plenty of vitamins and calcium.[74] When thus fed cottonseed meal is even satisfactory in rations for brood sows. If too much cottonseed meal is fed, disaster may result, even when the other feeds in the rations supply an abundance of carotene and calcium.

In some cases pigs have been fed rations containing as much as 30 per cent cottonseed meal without injury, because the cottonseed meal happened to be low in gossypol. However, feeding such a ration is very hazardous.

A combination of one-half to two-thirds cottonseed meal and the remainder tankage, meat scrap, or fish meal is an excellent supplement to corn or other grain for pigs or brood sows that are on pasture. When no more of such a mixture is fed than is needed to balance the ration, the proportion of cottonseed meal is kept within limits that are safe, and the animal by-products make good the deficiencies in the quality of protein in the grains and in cottonseed meal. Unless the mixture contains at least one-half tankage or fish meal, a calcium supplement should be fed, since cottonseed meal is low in this mineral. For swine that are not on pasture, some legume hay should be added to a ration of grain, cottonseed meal, and tankage or fish meal, in order to provide an abundant supply of vitamins. This is especially necessary where grains other than yellow corn are fed.

The excellent results that are secured when cottonseed meal is fed in combination with tankage or fish meal are shown by many experiments, both with pigs in dry lot and with pigs on pasture. In 25 comparisons pigs gained 1.52 lbs. per head daily when fed a combination of cottonseed meal and tankage as the protein supplement to grain, in comparison with 1.44 lbs. for others fed tankage as the only supplement.[75] In these experiments 100 lbs. of cottonseed meal were equal in value to 65 lbs. corn plus 43 lbs. tankage. In 13 similar experiments in which a combination of cottonseed meal and fish meal has been compared with fish meal as the only supplement, the cottonseed meal has had a similarly high value.[76] A combination of half cottonseed meal and half soybean oil meal is usually fairly satisfactory.

Cottonseed meal is a satisfactory substitute for linseed meal in the trio supplemental mixture for pigs not on pasture, which consists of 50 lbs. tankage or meat scrap, 25 lbs. linseed meal and 25 lbs. chopped or ground legume hay.

However, in 10 experiments in which the cottonseed-meal trio mixture has been directly compared with the linseed-meal trio mixture for young pigs in dry lot, the results have been slightly better on the latter.[77]

While low-gossypol cottonseed meal or that which has been treated with ferrous sulfate to destroy the free gossypol has not been satisfactory as the only protein supplement for growing and fattening pigs, in Florida experiments it produced nearly as good results as did soybean oil meal, when used as the supplement for sows on pasture.[78] For swine, even low-gossypol cottonseed meal should be fed in combination with meat scrap, tankage, fish meal, or soybean oil meal, which have more lysine.

819. Cottonseed meal for poultry.—In the southern states, where cottonseed meal is frequently the cheapest protein-rich feed, it is often used in poultry rations. Extensive experiments have therefore been conducted to determine the extent to which cottonseed meal can be used satisfactorily for poultry.[79]

Ordinary cottonseed meal can replace part of the meat scrap or other protein supplements of animal origin that would be needed to balance the ration. However, it should not be used as the chief protein supplement, because the quality of the protein is not high and also because of possible detrimental results.

If the ration of laying hens has more than about 5 per cent of ordinary cottonseed meal, the yolks of the eggs are apt to develop an olive green or brown color and the albumen a pinkish color on storage. Cottonseed meal processed so that it is very low in free gossypol can be fed in larger amounts to hens without injuring the storage quality of the eggs. Such cottonseed meal can be used satisfactorily as the chief protein supplement for chicks, in combination with some fish meal, meat scrap, dairy by-products, or soybean oil meal, and if sufficient vitamins and calcium are provided.

820. Cottonseed feed.—Cottonseed feed, which usually contains less than 36 per cent protein, is not only lower in protein than cottonseed meal, but it is also higher in fiber and lower in total digestible nutrients. This is because it contains an appreciable proportion of hulls. Cottonseed feed is sometimes sold for but a few dollars a ton less than the best grades of cottonseed meal. It is therefore important to note the fiber guarantee for any lot of cottonseed meal or cottonseed feed.

One can determine approximately the proportion of additional hulls in a sample of cottonseed feed by comparing its fiber guarantee with the average fiber figures shown in Appendix Table I for high-grade cottonseed meal and for cottonseed hulls. By appearance alone it is impossible to distinguish good cottonseed meal from finely ground cottonseed feed.

Cottonseed feed may be an entirely legitimate product, for it is sometimes impossible to separate thoroughly the hulls of certain kinds of cottonseed from the kernels. However, such feed should be bought at a price corresponding to its actual value. In a Pennsylvania test cottonseed meal was a much more economical supplement than cottonseed feed for fattening cattle, though the price of the cottonseed feed was 19 per cent less a ton.[80]

821. Whole-pressed cottonseed.—This by-product is made by pressing the whole cottonseed, including the hulls, in oil expellers. Since it contains all the hulls, it is much lower in protein and higher in fiber than cottonseed meal and has a correspondingly lower value. Generally, it is guaranteed to contain 28 per cent protein and has 22 to 25 per cent fiber. A safe basis of valuing this feed is to estimate from the guaranteed composition the amount of cottonseed meal and of hulls there are in each ton, and value each at the local price. Thus, a ton of whole-pressed cottonseed having 28 per cent protein will be about equal to 1,200 lbs. of 43 per cent protein cottonseed meal and 800 lbs. of cottonseed hulls.

Whole-pressed cottonseed may be fed to stock in the same manner as cottonseed meal or cake. In 4 Texas trials it was worth 73 per cent as much per ton as 41 per cent protein cottonseed cake for fattening cattle.[81]

822. Cottonseed.—Commonly but little cottonseed is fed to stock, but instead farmers sell the seed to the oil mills and buy cottonseed meal. This is both on account of the value of the oil and because cottonseed meal usually gives better results as a stock feed. However, when the price for cottonseed is unusually low in comparison with that of cottonseed meal, it is an economical feed. Animals fed too large amounts of cot-

tonseed may scour badly, on account of the large amount of oil. There is no advantage in grinding cottonseed for cattle, and it is difficult to grind it in some mills because of the high oil content.

Cottonseed supplies only about half as much digestible protein per pound as does 41 per cent protein cottonseed meal, but it has one-fourth more total digestible nutrients, because it is so rich in fat.

In trials with dairy cows it has required 171 to 206 lbs. of cottonseed to equal 100 lbs. of cottonseed meal.[82] In a Mississippi test whole cottonseed, fed in a dairy concentrate mixture, was slightly superior to a mixture of 4 parts ground corn and 3 parts cottonseed meal.[83] Because of the high fat content of cottonseed, the fat percentage of the milk was increased slightly. It is sometimes difficult to get cows to eat the seed, unless a more palatable feed, such as ground corn or wheat bran, is mixed with it. Cottonseed has an even more marked hardening effect than cottonseed meal on the character of butter.

For fattening cattle cottonseed is an economical substitute for part or all of the cottonseed meal in a ration when it is decidedly cheaper in price. In Texas and Arizona experiments it required 103 to 140 lbs. of cottonseed to equal 100 lbs. of cottonseed meal in value.[84]

In other Texas trials where cottonseed was fed as a substitute for one-third the ground milo grain in a ration for fattening cattle, the cottonseed was worth 48 per cent more a ton than milo.[85] Feeding as much as 6 lbs. a day to fattening cattle did not cause scours.

Though cottonseed is rarely fed to sheep, the results were satisfactory in Texas tests when 0.4 to 0.6 lb. cottonseed per head daily was fed to fattening lambs as the protein supplement, or as a substitute for part of the grain.[86] The results were poor on a ration of only cottonseed and cottonseed hulls.

Immature cottonseed, or bolly cottonseed, is much lower in protein and fat than mature seed. Its feeding value is correspondingly less.

823. Gin trash.—Gin trash, a by-product from cotton gins, is composed mostly of fragments of burs and stems, with small amounts of immature cottonseed, lint, leaf fragments, and dirt. In a Texas trial gin trash, fed with sorghum grain, alfalfa hay, and cottonseed meal, was fully equal to cottonseed hulls for fattening cattle.[87] In a Mississippi trial it was satisfactory for wintering beef steers when fed in addition to silage and 1 lb. cottonseed meal per head daily, but it did not give good results as the only roughage.[88]

824. Cottonseed hulls.—Cottonseed hulls are one of the important roughages in the South, especially for cattle, to which they are chiefly fed. They are also sometimes fed to sheep or work stock. Cottonseed hulls supply 43.7 per cent of total digestible nutrients, which is about as much as is furnished by late-cut grass hay or by oat straw. The hulls are very low in protein and practically none of it is digestible. The hulls are also low in calcium, are very low in phosphorus, and are lacking in carotene.

To correct their deficiencies, cottonseed hulls should be fed with protein-rich feeds and as only part of the roughage, along with good-quality legume hay or other forage that will supply the carotene and the minerals in which they are deficient. Unless they are fed with considerable legume hay, a calcium supplement should be used, such as ground limestone or oyster shells. Also, a phosphorus supplement should be added, unless sufficient of this mineral is furnished by a phosphorus-rich protein supplement, such as cottonseed meal.

When properly fed, cottonseed hulls are generally about equal in value to fair-quality grass hay and are worth more per ton than corn or sorghum stover, straw, or poor hay. The hulls are well liked by cattle, even when fed as the only roughage.

Cottonseed hulls are usually fuzzy, due to short lint which remains on the seed. Sometimes this lint is removed from the seed at the oilmills for paper making and other purposes, and the hulls from such seed are ground, being then called *cottonseed hull bran.* Though finely ground, the value of the product is not appreciably greater than that of ordinary hulls.

825. Cottonseed hulls for dairy cattle.—Because of their nutritive deficiencies, cottonseed hulls should not be fed to dairy cattle as the only roughage over long periods. They should be fed with

some well-cured hay (especially legume hay) or good silage in addition, or to cattle which are on good pasture a considerable part of the time. If cottonseed hulls are used as the chief roughage, a calcium supplement should be fed.

When cottonseed hulls were fed in Louisiana tests with silage and a concentrate mixture supplying plenty of protein and calcium, they were superior to late-cut Bermuda grass and carpet grass hay for dairy cows and nearly equal to good Bermuda grass hay.[89] In other experiments cottonseed hulls were worth somewhat less per ton than good corn stover, Bermuda grass hay, Johnson grass hay, Sudan grass hay or sorghum hay for dairy cows or heifers.[90]

When bulky concentrates, such as oats and wheat bran, are not available or are high in price, cottonseed hulls may be useful to increase the bulkiness of a mixture of heavy concentrates.

826. Cottonseed hulls for beef cattle.—Cottonseed hulls are used extensively for beef cattle in the South and are a satisfactory roughage if the ration provides sufficient protein, minerals, and carotene. Instead of being fed as the only roughage, cottonseed hulls had best be fed with silage or with well-cured hay, especially legume hay. Unless some legume hay is fed, a calcium supplement should be used.

When cottonseed hulls replaced part of the alfalfa hay in rations for fattening cattle, they were worth about two-thirds as much as the hay in Texas trials.[91] Adding the hulls to the ration helped prevent bloat. In New Mexico tests cottonseed hulls, fed with alfalfa hay, were not equal to ground hegari fodder for fattening cattle.[92] In other experiments cottonseed hulls have been worth somewhat less than prairie hay, Johnson grass hay, or peanut hay.[93]

In 9 Florida and Mississippi tests 100 lbs. of cottonseed hulls were equal to 273 lbs. of sorghum silage, but in 4 Georgia trials 100 lbs. of hulls were only worth as much as 126 lbs. of corn-and-sorghum silage.[94]

Years ago, cattle were commonly fattened in the South on nothing but cottonseed meal and cottonseed hulls. However, if this ration is continued for any long period, the results are often poor, because of the deficiencies that have been discussed earlier in this chapter. (**810–811**) Even during the usual fattening period, the results are considerably improved if well-cured hay or good silage is added to this ration to furnish carotene, and also a calcium supplement, unless legume hay is fed. When hay or silage is not available, even the calcium supplement alone is beneficial, though the cattle will be affected by the vitamin deficiency if the ration is continued too long.

If cattle have been on excellent pasture before being placed in the feed lot for fattening, they may do surprisingly well on a ration of only cottonseed meal and cottonseed hulls plus minerals. This is because they will then have a considerable store of vitamin A in their bodies. Cattle a year old or more will do much better than calves on cottonseed meal and hulls alone. In South Carolina experiments 700-lb. steers gained as rapidly for 100 to 150 days on cottonseed meal and hulls as on shelled corn and alfalfa or lespedeza hay and showed no evidences of nutritive deficiencies.[95]

827. Cottonseed hulls for sheep.—Cottonseed hulls are less useful for sheep than for cattle. In 3 New Mexico trials when cottonseed hulls replaced part of the alfalfa hay in a ration for fattening lambs, the gains were reduced decidedly and the hulls had a very low value.[96] In Kentucky trials lambs gained appreciably less when fed a mixture of corn, cottonseed meal, and cottonseed hulls, with a little alfalfa meal and molasses, than on a simple ration of alfalfa hay and corn.[97] Thus fed, the hulls were worth only about one-third as much as hay.

In the southern states fattening lambs are sometimes fed cottonseed hulls as the only or the chief roughage, with grain and cottonseed meal or with cottonseed meal as the sole concentrate. Such a ration produces much less rapid gains than grain and legume hay, and if

it is continued for more than about 60 days injury may result, due chiefly to the lack of carotene and of calcium.[98]

III. Flaxseed; Linseed Meal and Cake; Other Flax By-products

828. Flaxseed.—In this country flax (*Linum usitatissimum*) is grown almost entirely as a cash crop for the production of linseed oil from the seed. Our flax fiber is nearly all imported from countries where the cost of labor is lower, for much hand labor is required in the production and preparation of flax fiber of the best quality.

Most of our flaxseed is grown in the Dakotas and Minnesota. A smaller acreage is raised in Montana and Texas and under irrigation in California, with small amounts being grown elsewhere. During the past few years the acreage harvested in this country has ranged from 3,303,000 to 5,663,000 acres, with average yields per acre of 7.3 to 9.8 bushels, weighing 56 lbs. Some flaxseed is imported into the United States, especially from Argentina, and processed here for linseed oil.

But very little flaxseed is fed to livestock, because of its high value for linseed oil production. However, ground flaxseed is entirely satisfactory as a protein supplement in place of linseed meal. Though it contains only two-thirds as much protein as linseed meal, it is one of the richest of feeds in total digestible nutrients. On account of its high oil content (which averages 35.9 per cent), it supplies more than 100 lbs. total digestible nutrients per 100 lbs. (including digestible fat multiplied by 2.25).

In feeding experiments with fattening cattle, fattening lambs, and pigs ground flaxseed has usually been equal or slightly superior to linseed meal in feeding value.[99] If too much flaxseed is fed to pigs, soft pork may be produced. Ground flaxseed is sometimes used as an ingredient in calf meals.

It is of interest to note that the reserve food stored in flaxseed is largely oil and pentosans, no starch grains being found in well-matured seed. Very rarely flaxseed may contain a compound (a glucoside) which, when acted upon by an enzyme in the seeds, yields the poison, prussic acid. This enzyme is destroyed by the heat to which the ground flaxseed is ordinarily subjected in oil extraction. In making gruel or mash from untreated flaxseed, it is advisable to use boiling water and keep the mass hot an hour or two, to destroy any prussic-acid-forming enzyme in the seed.

829. Linseed meal or cake.—Linseed oil is now produced in this country by all three oil-milling methods—the hydraulic, or so-called "old process;" the expeller, or screw-press method; and the solvent process. (794) The linseed cake produced in the hydraulic process is commonly ground to form linseed meal, or is ground more coarsely to make nut-size or pea-size linseed cake. Sometimes solvent-process linseed meal is pelleted in various sizes.

In this book the term linseed meal will generally be used for both linseed meal and linseed cake. Linseed meal or cake is sometimes called merely *oil meal* or *oil cake*. These terms should therefore always mean the linseed product, unless another designation is used, as soybean oil meal, for example.

Linseed meal is one of the most popular protein supplements in this country. Its popularity is due not only to its richness in protein, but even more to its palatability and to its slightly laxative effect, which aids in keeping stock healthy. Also, it seems to have a conditioning effect on stock.

Linseed meal is excellent as the only protein supplement for dairy cattle, beef cattle, sheep, and horses. Because of its laxative nature, linseed meal is of especial value when little or no legume hay is fed and the roughage is of rather poor quality. Linseed meal is highly esteemed in fitting cattle for show or sale, for it aids in producing bloom and in making the hide mellow and the hair glossy.

For swine and poultry linseed meal should be used in combination with an-

other protein supplement which provides protein of better quality, such as meat scrap, tankage, fish meal, or dairy by-products. As is pointed out later, linseed meal has little usefulness in poultry feeding.

On account of its popularity, linseed meal is often a more expensive source of protein than some of the other protein supplements. It should then not be fed as the only protein supplement, but should be combined with the cheaper supplements and used for its particular laxative and conditioning effects.

Linseed meal made by the hydraulic or the expeller process from North American flaxseed usually has at least 34 per cent protein, and has 4 to 5 per cent of fat. Solvent-process linseed meal is generally guaranteed to have 36 per cent protein, but has an average of only 1.0 per cent fat. While it is higher than hydraulic or expeller linseed meal in digestible protein, it is appreciably lower in total digestible nutrients. Linseed meal made from Argentine flaxseed may not have over 30 to 31 per cent protein, as the flaxseed raised there is lower in protein.

Linseed meal or cake is sold primarily on the basis of its protein content, and the percentage of protein should be stated definitely in the trade name of the meal. For example, linseed meal guaranteed to contain 34 per cent protein is called "34-per cent-protein linseed meal." Separate averages are given in Appendix Table I for the various grades of linseed meal.

The protein of linseed meal does not effectively supplement the protein of corn or other grains for non-ruminants. In this respect it is of lower value than the protein in well-cooked soybean oil meal. (122–123) Linseed meal has a fair calcium content, averaging 0.37 per cent, and is rich in phosphorus, with an average of 0.86 per cent. Linseed meal does not supply carotene or vitamin D, but has a fair content of the B-complex vitamins.

830. Linseed meal for dairy cattle. —Linseed meal is one of the most popular dairy feeds, because of its richness in protein and particularly because of its palatability and its conditioning and slightly laxative effects. For these reasons, many dairymen include at least 5 to 10 per cent of linseed meal in the concentrate mixture they feed their cows, even when other feeds, such as cottonseed meal or gluten feed, are cheaper sources of protein. Linseed meal is especially valuable when there is no succulent feed in the ration and little or no legume hay. It is likewise widely used as part of the concentrate mixture for cows on official test and in preparing cows for freshening. Linseed meal is also excellent for dairy calves and heifers.

Experiments have shown that when linseed meal is fed with good-quality roughage, so that its conditioning effect is not needed, it is worth slightly less per ton than cottonseed meal as a source of protein, because it is lower in digestible protein.[100] On the other hand, with poor roughage linseed meal would be worth more per ton than cottonseed meal. Linseed meal tends to produce soft butter, and therefore improves rations that would otherwise produce a hard, tallowy product.

In 2 Ohio trials solvent-process linseed meal was about equal to expeller-process as the protein supplement for dairy cows.[101] The hair of the cows fed the solvent oil meal was as glossy as that of the cows fed the expeller oil meal, and in this and in a Wisconsin test there was no difference in the palatability of the concentrate mixtures containing the different oil meals.[102]

831. Linseed meal for beef cattle. —Throughout the northern states linseed meal and mixtures including linseed meal are widely used as protein supplements for beef cattle. Linseed meal is of particularly high value for fattening cattle, because it produces rapid gains and excellent finish. Cattle fed linseed meal usually have a trifle sleeker coats than those fed other common protein supplements. They therefore tend to sell for a slightly higher price on the large markets, though the actual value of their carcasses may be no greater. Because of this conditioning effect, linseed meal is

commonly included in concentrate mixtures for cattle that are being fitted for show or for sale. Linseed meal is also excellent for young stock or breeding cattle.

Although cottonseed meal is richer than linseed meal in protein, linseed meal usually has a decidedly higher value per ton when fed as the only protein supplement to fattening steers, if the cattle are sold on a discriminating market. In 42 experiments fattening cattle fed linseed meal as the only supplement gained an average of 2.29 lbs. per head daily, while those fed cottonseed meal averaged 2.20 lbs.[103] The cattle fed linseed meal also required slightly less feed per 100 lbs. gain. Considering only this factor, cottonseed meal would have been worth about 89 per cent as much as linseed meal in these trials.

However, in nearly all of the experiments the cattle that had been fed linseed meal sold for a slightly higher price, either because of better finish or a sleeker appearance. On the average, there was a difference of 16 cents per hundredweight in selling price in favor of the linseed-meal-fed cattle. Though this difference may seem small, it is of importance, because it applies to the entire weight of the cattle when they are marketed.

Primarily because of this difference in average selling price, the average net return per head over cost of feed was distinctly higher for the cattle fed linseed meal, even though the cost of the linseed meal was $4.09 per ton higher than that of the cottonseed meal.

Taking both the difference in selling price and the difference in amounts of feed required per 100 lbs. gain into consideration, in these experiments it would have been necessary to buy cottonseed meal at only 62 per cent of the price of linseed meal to make an equal net profit per head.

These experiments do not mean that cottonseed meal is not satisfactory as the only protein supplement for fattening cattle. However, they show that linseed meal produces slightly more rapid gains and appreciably better finish. When the cattle are sold on a discriminating market, the difference in selling price is sufficient to give a decidedly higher value per ton to linseed meal, because only a relatively small amount of supplement is needed to balance most rations.

In contrast to these results with fattening cattle, are Kansas experiments in which beef calves or yearlings were wintered on Atlas sorghum silage, or sorghum silage and prairie hay, supplemented with 1 lb. per head daily of linseed meal, cottonseed meal, or soybean oil meal.[104] The cattle made slightly better gains on cottonseed meal or soybean oil meal than on linseed meal, perhaps because 1 lb. a day of linseed meal did not supply as much protein as the same weight of the other supplements. When the other feeds in a ration are very laxative, cottonseed meal will also be superior to linseed meal, as has been mentioned previously. (814)

Solvent-process linseed meal is of only slightly lower value than expeller-process or hydraulic-process linseed meal for fattening cattle. In 5 experiments fattening cattle fed solvent-process linseed meal as the protein supplement gained an average of 2.08 lbs. a day, in comparison with 2.15 lbs. for others fed that made by the expeller or the hydraulic process.[105]

832. Combining cottonseed meal and linseed meal.—Some years ago, after the author and associates had compared cottonseed meal and linseed meal in experiments with fattening steers, it occurred to him that a mixture of one-half linseed meal and one-half cottonseed meal might be fully equal to linseed meal alone. Accordingly, experiments were conducted at the Wisconsin Station to study this question, and similar tests were carried on later at the Iowa and Kansas Stations.[106] In 9 trials the gains were fully as rapid on the combination of cottonseed meal and linseed meal as on linseed meal fed as the only supplement. Though the selling price averaged 13 cents per hundredweight higher on the latter ration, slightly less feed was required per 100 lbs. gain on the mixed supplement. Considering all factors, the

average value per ton of the cottonseed meal-linseed meal mixture was 97 per cent that of linseed meal.

These trials show that although under most conditions linseed meal is considerably superior to cottonseed meal as the only supplement for fattening cattle, a mixture of these two supplements is practically equal to linseed meal in value.

833. Linseed meal for sheep.—Linseed meal is deservedly a very popular protein supplement for fattening lambs and the breeding flock. Because of the excellent results secured with linseed meal, it may well be taken as the standard with which other supplements are compared.

As has been shown earlier in this chapter, when there is considerable legume hay in the ration, cottonseed meal is practically equal to linseed meal as a protein supplement for fattening lambs. (816) However, if the lambs are fed little or no legume roughage, linseed meal is superior.

In a Minnesota trial with fattening lambs there was no appreciable difference in the value of linseed meal made by the hydraulic, the expeller, or the solvent process, and in a Nebraska trial solvent and expeller linseed meals were of equal value.[107]

834. Linseed meal for horses and mules.—Linseed meal is an excellent protein supplement for horses and mules. It is especially useful, because of its laxative and tonic properties, for bringing into condition rundown horses with rough coats, and it gives bloom and finish in fitting horses for show or sale.

Not over 1 to 1.5 lbs. of linseed meal per head daily are needed to balance such a ration as corn and timothy hay. In an Iowa test a mixture of 1 part of linseed meal to 16 parts of corn and oats was very satisfactory for feeding with timothy hay to horses at hard work.[108] Too large a proportion of linseed meal is unduly laxative for hard-worked horses.

835. Linseed meal for swine.—Linseed meal is an excellent protein supplement for swine, when it is fed in combination with such animal by-products as tankage, fish meal, or skimmilk. For example, it produces excellent results when used in trio-type mixtures for pigs not on pasture, discussed in Chapter XXXIV. If used as the only protein supplement to corn or other grain in swine feeding, linseed meal is much less efficient than feeds that supply protein of better quality.

Linseed meal produces fairly satisfactory results when fed as the only protein supplement to growing and fattening pigs on good pasture, but the gains are less rapid than when a more efficient supplement is used. In 9 experiments 59-lb. pigs fed corn and linseed meal on alfalfa pasture or rape pasture gained 1.29 lbs. per head daily, while others fed corn and tankage gained 1.34 lbs.[109] When linseed meal was thus fed, it was worth about 55 per cent as much per ton as tankage.

Such a ration as corn and linseed meal is decidedly unsatisfactory for young pigs not on pasture, even if a calcium supplement is added to correct the lack of this mineral in both grain and linseed meal. For example, in 5 experiments pigs thus fed gained only 1.08 lbs. per head daily, while others fed corn and tankage gained 1.37 lbs.[110] In these trials 100 lbs. of linseed meal were worth only as much as 66 lbs. tankage minus 100 lbs. corn.

Even for well-grown pigs, linseed meal is not efficient when fed as the only protein supplement to corn or similar grain. Where no animal by-products, like tankage, fish meal, or dairy by-products, are available to feed with linseed meal and grain to pigs not on pasture, much better results will generally be secured if legume hay is added to the ration, even when the grain is yellow corn.[111] However, in the case of young pigs, the gains will be much less rapid and economical on a ration of corn, linseed meal, and alfalfa hay than when tankage or some other animal by-product is included in the ration.

Linseed meal is much more satisfactory as the only protein supplement to

barley or wheat than as a supplement to corn.[112]

836. Linseed meal for poultry.—In striking contrast to the excellence of linseed meal as a feed for cattle, sheep, and horses, it is not satisfactory when forming any important part of the rations for laying hens, chicks, or other poultry.[113] Linseed meal has not generally given good results in poultry feeding, even when combined with protein supplements of high quality, such as fish meal and milk by-products.

As little as 5 per cent of linseed meal has depressed the growth of chicks, when included in a ration otherwise satisfactory.[114] A ration containing 10 per cent of linseed meal caused the death of all the turkey poults to which it was fed.[115] The injurious effects of linseed meal can be prevented by soaking or autoclaving it, or by adding the vitamin pyridoxine to the ration.[116]

In view of the popularity and high value of linseed meal for feeding other classes of stock, it hardly seems wise to include it in poultry rations under any usual conditions.

837. Other flax by-products.—*Flaxseed screenings oil feed* is the ground product obtained after extraction of part of the oil from the smaller, imperfect flaxseed, weed seeds, and other material separated in cleaning flaxseed. The composition and value of this feed and also of flaxseed screenings vary widely.

Sometimes the screenings are not removed thoroughly from the flaxseed before it is processed, or screenings oil feed is added to the linseed meal. Such products must be sold as *linseed feed* and not as *linseed meal.* Since the feeding value of linseed feed will often be much less than that of linseed meal, one should read carefully the name on the tag or sack and note the guaranteed composition. Otherwise, he may pay a linseed-meal price for an inferior product. In certain cases such flaxseed by-products may contain so much bitter-tasting weed seeds that they are decidedly unpalatable to stock, and they may even produce an off-flavor in the milk of cows.

Flax plant by-product is that portion of the flax plant remaining after harvesting the seed and separation of the bast fibers and flax shives. It consists of the leaves, corticle tissues (bark and outer portions) of the stems, flax seed bolls, and immature seeds. According to the definition proposed by the Association of American Feed Control Officials, flax plant by-product should have at least 9 per cent protein and not over 35 per cent fiber.[4] However, even 35 per cent fiber is more than hay of fair quality usually contains.

This low-grade product is used in certain cheap formula feeds for cattle and sheep. It is a good absorbent for molasses.

IV. Various Legume Seeds and By-products

838. Peanuts.—Peanuts (*Arachis hypogaea*), called earth nuts in some countries, are an important crop in the southern states, being grown chiefly for human consumption as peanuts, peanut butter, or peanut oil. However, a considerable acreage is grown for hogging down, and also swine are often turned in to clean up any remaining nuts, after a crop of peanuts has been harvested. Unfortunately, as is discussed later, peanuts produce soft pork, though the pork is otherwise of good quality. When available, peanuts can also be used in limited amounts as a protein supplement for other classes of stock. "Peanut hay," which remains after the nuts are picked from the cured vines, has been discussed in Chapter XVI.

The acreage of peanuts grown for nuts in this country has been only about 1,450,000 acres during recent years, which is small in comparison with that of soybeans. The average yield of unshelled peanuts for a 10-year period was 792 lbs. per acre.

Whole peanuts, including the hulls, or shells, have an average of about 25 per cent of protein, which is of good quality. Though unhulled peanuts are high in fiber, they are very rich in total digestible nutrients, because of their fat content of 36 per cent. Like soybeans, peanuts are deficient in carotene and vitamin D, are low in calcium, and are not very rich in phosphorus. On exposure to the air, shelled peanuts soon become rancid.

Pigs fed whole harvested peanuts without other concentrates make very

satisfactory gains if supplied with salt and also a calcium supplement, such as ground limestone or oyster shell. For example, in 3 Florida experiments pigs thus fed gained 1.0 lb. per head daily on the average. They required only 201 lbs. of feed per 100 lbs. gain, because of the high content of total digestible nutrients and of net energy in the fat-rich peanuts.[117] If the salt or calcium supplement is omitted, the results are very poor. For young pigs raised in dry lot without any green feed, it would be advisable to supply well-cured legume hay in addition, to make sure of a sufficient vitamin supply.[118] The amounts of peanuts that can be fed without producing soft pork are stated in Chapter XXXIV.

In Alabama tests mature chickens would eat whole peanuts after they became used to them, without picking out the kernels.[119] For laying hens there was no advantage in grinding peanuts. When hens were fed considerable amounts of shelled peanuts, the results were poor, perhaps because of the high fat content.

SPANISH TYPE OF PEANUTS

Nearly one-third the acreage of peanuts in this country is commonly hogged down, though soft pork is produced by this method. (From U.S. Department of Agriculture.)

839. Hogging down peanuts.—In spite of the fact that hogging down peanuts produces soft pork, nearly one-third of the peanut acreage in this country is commonly thus harvested by turning pigs into the field to root out the nuts. This is because the method is a very cheap way of fattening pigs. Experiments have shown that it is very important to supply pigs hogging down peanuts with salt and a calcium supplement, or even a more complete mineral mixture.[120] Pigs may make a little more rapid gains when fed tankage or meat scrap in addition to the peanuts and peanut forage they get, but the gains may be fully as cheap without the animal-protein supplement.

Spanish peanuts are grown for hogging down in the early fall, as they sprout badly after maturity and must be hogged off in 4 to 6 weeks. Runner peanuts keep well in the ground until January or February. In trials during 7 years in Georgia, runner peanuts hogged down produced an average of 388 lbs. gain per acre, in comparison with 417 lbs. for corn and 462 lbs. for sweet potatoes, also hogged down.[121] However, much more labor is required to grow sweet potatoes than for peanuts. In Florida tests Spanish peanuts or runner peanuts did not so closely approach corn or sweet potatoes in the amount of pork produced per acre, as in the Georgia trials.[122]

Brood sows or very young pigs are not

commonly turned on a fresh peanut field, because large amounts of peanuts are said to be injurious to them. However, they can clean up the fields after peanuts have been dug for market, or after the fattening hogs have eaten most of a crop.

840. Peanut oil meal; peanut meal and hulls.—*Peanut oil meal* or *cake* is the by-product from the production of oil from peanuts which first have been well hulled or shelled. According to the definition of the Association of American Feed Control Officials, peanut oil meal should not have more than 7 per cent of fiber. If the fiber content is higher than this, it shows that the peanuts have not been well hulled, or that hulls have been added. Such a product should be sold as *peanut meal and hulls*, according to the official definition. However, much of the peanut oil meal on the market has considerably more than 7 per cent fiber.

Peanut oil meal of the 45 per cent protein grade, made from well-hulled peanuts, has an average of 46.6 per cent protein and only 5.5 per cent fiber. *Peanut meal and hulls* of the 41 per cent protein grade has 41.1 per cent protein, but has an average of 15.0 per cent fiber, and therefore supplies considerably less total digestible nutrients (73.3 per cent). Since the fiber content of feed sometimes sold as peanut oil meal varies widely, depending on the amount of hulls, one should carefully note the fiber guarantee before purchasing. A product having 15.0 per cent fiber will contain about 15 per cent more peanut hulls than peanut oil meal made from well-hulled peanuts. The value will be correspondingly less, because peanut hulls have little feeding value.

In compiling the analyses for Appendix Table I, feed called *peanut oil meal*, but having more than 7 per cent fiber, has been properly classed as *peanut meal and hulls.*

Peanut oil meal of 45 per cent protein grade has 42.4 per cent digestible protein and 84.5 per cent total digestible nutrients, thus being higher in both than is soybean oil meal. Peanut meal and hulls of the 41 per cent protein grade, expeller or hydraulic process, has 36.6 per cent digestible protein and 73.3 per cent total digestible nutrients, being slightly higher in both than cottonseed meal of the 41 per cent protein grade.

The quality of the protein of peanut oil meal is good, ranking close to that of soybean oil meal. However, it usually has less lysine than does soybean oil meal.

Peanut oil meal is low in calcium and has only about half as much phosphorus as cottonseed meal. It lacks carotene and vitamin D, like most other seed products. It is fair in content of thiamine, low in riboflavin, and especially rich in niacin and in pantothenic acid.

Peanut oil meal is one of the best protein supplements for livestock feeding. This is due not only to its richness in protein and total digestible nutrients, but also because it is well liked by stock and because the protein is of high quality. Peanut oil meal from well-hulled nuts generally equals or closely approaches soybean oil meal in value for dairy cattle, beef cattle, sheep, horses, and swine, and is of only slightly lower value for poultry.

Peanut oil meal tends to become rancid if stored too long, especially in warm, moist climates. In the South it should not be stored more than 2 to 3 months in cool weather and about 6 weeks in summer.

Since peanut hulls have but little feeding value, the worth of *peanut meal and hulls* will depend on the proportion of hulls contained. This can be estimated from the guaranteed fiber content.

841. Value of peanut oil meal for various classes of stock.—Peanut oil meal is most commonly fed to dairy cattle, and it is a very popular feed for milk cows in sections where it is available. In Georgia and Virginia experiments peanut oil meal was fully equal to soybean oil meal or cottonseed meal as the protein supplement for milk production.[123] It is somewhat laxative and when high in fat may be too laxative if it forms more than one-fourth of the concentrate mixture.

In several experiments with fattening cattle peanut oil meal has generally

been fully equal to cottonseed meal in value and equal or nearly equal to soybean oil meal.[124] On the other hand, in each of 3 Kansas experiments with beef calves and 3 with yearlings wintered on Atlas sorghum silage plus 1 lb. of protein supplement per head daily, peanut oil meal was slightly but distinctly inferior to cottonseed meal, soybean oil meal, or linseed meal.[125]

Peanut oil meal has been about equal to cottonseed meal or linseed meal as the protein supplement for fattening lambs.[126] It is also a very satisfactory protein supplement for horses or mules.

Peanut oil meal is an excellent protein supplement for swine.[127] If a calcium supplement is provided, it is satisfactory as the only protein supplement for pigs or brood sows on good pasture or for well-grown pigs in dry lot. For very young pigs in dry lot it is best to use peanut oil meal in combination with tankage, fish meal, or dairy by-products. A mixture of one-half peanut oil meal and one-half tankage, meat scrap, or fish meal produces fully as good results as an animal-protein supplement fed as the only supplement. Used as the only protein supplement for pigs fed corn or corn and alfalfa hay in 5 tests, 100 lbs. of peanut oil meal produced nearly as rapid gains as did tankage.[128] Each 100 lbs. of peanut oil meal replaced 51.6 lbs. tankage and 55.0 lbs. corn in feeding value. *Peanut meal and hulls* had a considerably lower value than this in 3 tests.[129]

Peanut oil meal is so palatable to pigs that they will eat much more of it than they need to balance their ration when self-fed corn and peanut meal separately, free-choice. This can be prevented by mixing ground corn and the peanut oil meal in the desired proportion. When peanut oil meal is low in price, a large proportion is sometimes included in the ration. However, feeding only 2 or 3 pounds of corn to each pound of peanut oil meal often produces soft pork. When fed in a larger proportion than needed to balance the ration, the additional peanut oil meal is only equal to corn in value per pound.

Peanut oil meal can be used in much the same manner as soybean oil meal for poultry.[130] Like soybean oil meal, it gives the best results when fed in combination with protein supplements of animal origin, such as meat scrap, fish meal, or milk by-products. It was concluded from North Carolina studies that at least one-half of the animal-protein supplements in mashes for laying hens can be replaced satisfactorily with peanut meal.[131] Peanut oil meal is not satisfactory as the only protein supplement, or when as much as 30 to 35 per cent is used in a chick ration to replace all the soybean oil meal.[132]

842. Peanut skins.—Peanut skins, also called peanut bran, are the by-product consisting of the thin red-brown covering of the kernels, together with more or less of the germs and broken bits of the kernels. Peanut skins have an average of 16.3 per cent protein, 23.9 per cent fat, and 11.8 per cent fiber. They are used chiefly in certain mixed feeds. Peanut skins were satisfactory as a substitute for wheat bran in Pennsylvania tests, when 20 per cent was included in the concentrate mixture for dairy cows.[133] As peanut skins are bitter in taste, they should be mixed with better-liked feeds.

843. Peanut hulls.—Peanut hulls, or shells, are a by-product at the factories making peanut butter, shelled peanuts, or peanut oil from shelled nuts. Commercial peanut hulls usually contain fragments of kernels and therefore have a little more protein and fat than the pure hulls.

Peanut hulls have an average of 6.7 per cent protein, considerably more than in cottonseed hulls, but they are extremely high in fiber, averaging 60.4 per cent. As a result, they supply only 18.8 per cent total digestible nutrients, which is far less than in straw.

In recent Texas and Virginia trials with beef cattle peanut hulls, ground very fine through a 1/8 to 3/8 inch screen, gave fair results when mixed with the concentrates, so they would be consumed readily.[134] In the Texas trials there were wide variations in the gains and finish of individual fattening cattle when ground peanut hulls formed any large part of the roughage.

844. Beans; cull beans.—Several varieties of beans (*Phaseolus*, spp.) are raised in this country for human food. These include ordinary field or navy beans, lima beans,

kidney beans, and the pinto beans and tepary beans of the Southwest. All of these varieties have the same general composition and feeding value. In amount of total protein and other nutrients beans closely resemble field peas. However, their feeding value is much lower. Beans are not very palatable to stock; their digestibility is not high when they are fed raw, especially to swine; and their protein is not of good quality.

The *cull beans* which are sorted out from the first-quality dry beans can be used satisfactorily for stock feeding, if attention is paid to their limitations. Such cull beans include not only discolored, shrunken, and broken beans, but also more or less waste, such as broken bits of stems, small stones, and dirt.

Ground cull beans can be fed to dairy cows as a substitute for other protein supplements, if they form not over about one-fifth of the concentrate mixture. Thus fed in Michigan experiments, they were worth about one-half as much as cottonseed meal per ton.[135] Unless the ground beans were mixed with palatable feeds, there was difficulty in getting the cows to clean up the feed. When beans are cooked, larger amounts can be fed to cows but this involves considerable expense.

For fattening cattle, the results were satisfactory when cull beans formed 16 per cent of the concentrate mixture, but poor when the grain mixture had 26 per cent of beans.[136]

Whole uncooked cull beans are suitable for fattening lambs when forming not more than 20 to 25 per cent of the concentrate mixture. A larger amount is apt to be unpalatable and to cause scours. The value of cull beans, fed to fattening lambs in such a mixture with barley and with alfalfa hay for roughage, has ranged from about 82 per cent of that of barley to fully equal to barley.[137]

In New York experiments there has been a decided benefit from adding 0.1 lb. linseed meal a day to corn and cull beans for fattening lambs.[138] In another New York experiment lambs made just as rapid and economical gains when cooked cull beans replaced all the corn or two-thirds the corn in a ration of corn, legume hay, corn silage, and 0.1 lb. linseed meal.[139] Lambs fed uncooked cull beans as the only concentrate have not made good gains and have required much feed per 100 lbs. gain.[140]

In Michigan tests cull beans were a satisfactory substitute for cottonseed meal as the protein supplement in rations for wintering breeding ewes.[141] Feeding too large a proportion of cull beans to breeding ewes may cause the "stiff lamb disease."

Cull beans give good results in swine feeding when thoroughly cooked and fed with grain, and preferably with an efficient protein supplement, such as tankage, meat scrap, or fish meal. In Michigan trials cooked cull beans (weighed before cooking) were worth 89 per cent as much as corn when 2 parts of beans and 1 part of corn were fed with tankage, alfalfa hay, and a mineral mixture.[142] In a California test cooked cull lima beans were about equal to ground barley in value when forming 15 to 30 per cent of a well-balanced ration.[143] Dry heating of the beans was not satisfactory, instead of boiling or steaming. In a Colorado test well-grown pigs gained as well on a ration of corn, cooked pinto beans, and alfalfa hay as others fed soybean oil meal in place of the beans.[144]

Beans are not commonly fed to poultry, but in a California test cull beans were used successfully to replace grain, when forming as much as 10 per cent of the ration for chicks.[145] For poultry it is best to cook beans and use them as part of a wet mash.

Mung beans (*Phaseolus aureus*) have recently increased rapidly in acreage in Oklahoma and surrounding districts, being grown as a late-sown cash crop to follow small grain. The green variety is grown mostly for seed production for human food, and especially for the preparation of bean sprouts. The cracked and cull beans cannot be used for sprouting and are used for stock feeding. Yellow mung beans are grown chiefly for forage. (493)

Extensive trials with mung beans at the Oklahoma Station show their value to be as follows: [146] When forming 30 per cent of the concentrate mixture for dairy cows, 100 lbs. of ground mung beans satisfactorily replaced 50 lbs. of corn and 50 lbs. of cottonseed meal. When substituted for cottonseed meal or cake as the protein supplement for fattening calves, the gains were as rapid and 100 lbs. of mung beans were equal in feeding value to 60 lbs. of cottonseed meal or cake plus 64 lbs. corn and 13 lbs. silage.

Mung beans were digested about as well by lambs as common protein supplements, but were not palatable when more than 0.35 lb. a day was fed. Ground mung beans could replace cottonseed meal in the trio supplemental mixture for pigs. For poultry, mung beans were satisfactory when forming as much as 30 per cent of the mash, provided it had proper protein, mineral, and vitamin

supplements. Cooking mung beans did not improve the value much for poultry. Mung beans could be used to replace two-thirds of the soybean oil meal and cottonseed meal in a ration for turkey poults.

845. Carob beans.—Carob beans (*Ceratonia siliqua*), also called algaroba or St. John's bread, are produced by a legume tree grown chiefly in Mediterranean districts. The seeds are imbedded in a thick, fleshy pod, rich in sugars, which forms about 89 per cent of the fruit.[147] The ground pods and seeds form *carob-bean meal,* which is used chiefly in certain mixed feeds, especially calf meals. It contains only 5.5 per cent protein, thus differing from most legume seeds.

In a California test crushed carob beans and pods were equal to ground barley as part of the ration for dairy calves.[148] In another California trial even 5 per cent of ground carob beans and pods was unsatisfactory in a ration for chicks.[149] In Hawaiian trials pigs made fair gains on a ration containing 70 per cent ground dehydrated carob beans and pods, and young turkeys over 8 weeks old made good gains when fed scratch grain and a mash having 25 per cent carob-bean meal.[150] Pigs did not do well on a ration containing 60 per cent chopped sun-dried carob beans.

846. Chick peas.—Chick peas (*Cicer arietinum*), also called gram or garbanzos, are grown for human food and also for stock in an extensive area from India to southern Europe and northern Africa, and in other warm regions. Chick peas resemble field peas in composition, but are slightly lower in protein and somewhat higher in fat.

847. Cowpeas.—The use of the cowpea (*Vigna sinensis*) for forage has already been discussed in Chapter XVI. The seeds of most varieties of cowpeas ripen unevenly, and therefore when the crop is grown for seed it is necessary to pick the pods by hand as they ripen, or else the plants are cut when about three-fourths of the pods are ripe, and before the first ones are shattered or damaged. For this reason cowpeas are used mostly for forage or for the production of seed for human food. However, some varieties of cowpeas can be combined for seed, with yields of 500 to 600 lbs. per acre.

In composition, cowpea seed is similar to field-pea seed. Cowpeas furnish protein of fair quality to supplement the cereal grains and may be used satisfactorily as a protein supplement in feeding cattle, sheep, horses, or swine. In 3 Oklahoma experiments fattening calves made about as good gains with 2.5 lbs. per head daily of ground cowpeas for the protein supplement as with 1.5 lbs. cottonseed cake.[151] The ground cowpeas were worth 59 per cent as much as cottonseed cake. For swine feeding, cowpeas had best be fed in combination with some other supplement that supplies better-quality protein.[152]

848. Guar.—Guar (*Cyamopsis psoraloides*), which has been mentioned previously in Chapter XVI, is a drouth-resistant legume that has been grown for centuries in India, for both human and animal food. The seed is a source of vegetable gum used as a thickener in salad dressings and other foods, and also used in industry.

In a trial by the United States Department of Agriculture rolled guar seed was a satisfactory protein supplement for steers, but in a Rhode Island test even 100 lbs. per ton of a by-product from producing vegetable gum from guar beans was unsatisfactory in a chick mash.[153]

849. Horse beans.—The horse bean (*Vicia faba*), or broad bean, is used in Europe to some extent for feeding stock, especially horses, as well as for human food. This legume grows fairly well in some parts of Canada, but has never proved a success in the United States, except in the central coast district of California. Horse bean seeds are similar in composition and feeding value to field peas. In Canadian trials ground horse beans were not satisfactory as the only protein supplement in a chick ration, but gave good results when combined with fish meal, meat meal, soybean oil meal, or linseed meal.[154]

850. Legume seed screenings.—*Alfalfa seed screenings* consist chiefly of the shriveled or light-weight alfalfa seeds removed in cleaning alfalfa seed, along with varying amounts of weed seeds, bits of alfalfa leaves and stems, etc. Screenings that contain but little low-grade material have an average of 31.1 per cent protein, 9.9 per cent fat, and 11.1 per cent fiber.

The screenings should be finely ground before feeding, to make them more digestible and to prevent infestation of the land with weeds. They are not very palatable to stock, but a limited amount can be satisfactorily included in a mixture of better-liked feeds. When forming one-quarter of the concentrate mixture for dairy cows in Idaho trials, each 100 lbs. of ground alfalfa-seed screenings replaced 57 lbs. of linseed meal and 42 lbs. of barley and wheat bran.[155]

Sweet-clover screenings are generally lower in protein and higher in fiber than alfalfa-seed screenings, and vary rather widely in composition. North Dakota tests show that the ground screenings may be used as part of the concentrates for stock in the same manner as alfalfa-seed screenings, a good grade being equal or superior to wheat bran in feeding value.[156]

Red- or alsike-clover-seed screenings resemble alfalfa-seed screenings in composition and may be used similarly.[157]

851. Lespedeza seed.—The annual lespedezas usually produce 300 to 500 lbs. of seed per acre and sometimes considerably more. The seed is as rich as linseed meal in protein and is a satisfactory protein supplement for stock feeding, when a surplus is available. It should be ground for cattle or swine, but need not be for sheep or poultry.

In a Missouri experiment with dairy cows ground lespedeza seed was equal to a mixture of cottonseed meal and soybean oil meal, when substituted for these feeds on an equal protein basis.[158] In Illinois and Missouri tests lespedeza seed was about equal to cottonseed meal or soybean oil meal for fattening lambs.[159] Ground lespedeza seed did not give quite as good results for fattening cattle in a Missouri trial, perhaps because there was difficulty in grinding it so as to crush all the seeds.[160]

Ground lespedeza seed is satisfactory as 10 to 20 per cent of a ration for chicks, replacing this much soybean oil meal.[161] In a Kentucky trial lespedeza seed and screenings containing 28 per cent protein was used successfully to replace as much as half the meat scrap in a ration for chicks or laying hens.[162]

852. Locust pods.—The pods of the honey locust (*Gleditsia triacanthos*) are high in sugar, like those of carob beans, and may be used similarly in stock feeding. In Alabama tests two varieties of thornless honey locust trees yielded at the rate of 1,266 to 2,798 lbs. of pods per acre when 5 years old.[163] Ground honey locust pods and seeds were a satisfactory substitute for oats in a concentrate mixture for dairy cows, and were very palatable.

853. Lupine seed.—The seed of most varieties of lupines (*Lupinus*, spp.) is poisonous to animals because of toxic alkaloids contained in it. However, varieties of yellow and blue sweet lupines have been developed which have little or no poisonous properties. In Florida and Georgia trials with fattening cattle ground sweet lupine seed was fairly satisfactory as a substitute for cottonseed meal, but was less palatable.[164] In another Florida test it did not give good results as the only protein supplement for chicks, but was fairly satisfactory when combined with soybean oil meal.[165] In English tests such sweet yellow lupine seed was satisfactory for dairy cows when as much as 5 lbs. were fed a day, for pigs when forming 10 per cent of the ration, and for poultry when forming 11 to 20 per cent of the feed.[166]

854. Mesquite pods and beans.—Mesquite (*Prosopsis juliflora*) and tornillo, a related species, are large leguminous shrubs or small trees common in certain sections of the southwestern states. Often these produce abundant crops of pods which are eaten by stock when they fall to the ground. The seeds are so small and hard that they largely escape digestion, unless the pods and seeds are ground finely. This is difficult, because of the high sugar content of the pods.

In New Mexico trials with sheep and pigs the value of mesquite and tornillo pods and beans varied widely, but on the average they were worth only about 40 per cent as much as grain.[167]

855. Peas; pea feed.—The acreage of *peas* (*Pisum sativum*, or *arvense*) raised in this country for the production of seed for stock feeding is very small, because the small grains generally yield a much greater weight of seed per acre. However, a considerable acreage of peas is raised for dry peas for human food and for seed peas in the northwestern states, especially in Washington and Idaho. The cull peas, consisting of split, small, or damaged peas, are used for livestock feeding, and may be practically equal to high-grade peas in feeding value. Cowpeas are often called peas in the South, but are a different legume.

As has been pointed out in Chapter XVI, peas are often grown with oats for hay, pasture, or silage. Also, field peas are raised sometimes in certain mountain valleys of the West, and the entire crop harvested by lambs or hogs which are grazed on it. Sometimes a combination of barley, oats, and field peas is grown for grain in the northern states.

Peas are raised chiefly in the northernmost states and other regions where the climate is cool, as they do not thrive unless the spring and summer temperatures are moderate. The average yield of peas in the United States for the 12-year period, 1943–1954 was 1,247 lbs. per acre.

Peas are relished by stock and are an excellent feed, when not too high in price. They have nearly as much protein as corn

gluten feed and furnish slightly more total digestible nutrients. Differing from soybeans, peas are low in fat, having an average of only 1.2 per cent. Peas are low in calcium and only fair in phosphorus, with a content of 0.50 per cent. The seed of green varieties equals yellow corn in carotene content (vitamin A value), and even yellow varieties have an appreciable amount. Peas lack vitamin D.

The protein of peas supplements that of the cereal grains to a considerable extent, but not so completely as does the protein of soybean oil meal. This is because peas are low in methionine, the essential sulfur-containing amino acid.[168] (**110**) However, peas give good results when fed as the only protein supplement to dairy cattle, beef cattle, sheep, or horses,[169] or to pigs on pasture. There is no appreciable difference in the value of green, yellow, or black (Austrian) peas.

Peas supply about as much digestible protein and total digestible nutrients as a mixture of one-half linseed meal and one-half barley, and are about equal to such a mixture in feeding value. Peas are excellent as part of the concentrate mixture in fitting sheep for show, because they produce firm flesh.[170] Peas should be ground for cattle and swine.

For pigs on pasture, peas give excellent results when used as the only supplement to grain, if calcium and phosphorus supplements are supplied.[171] For pigs in dry lot in Washington experiments, ground peas were also satisfactory as the only protein supplement to a mixture of ground barley and wheat, fed with alfalfa meal and a mineral mixture supplying calcium and phosphorus.[172] On the other hand, in similar Idaho trials peas did not produce as rapid gains, when fed as the supplement to ground wheat, as were obtained when peas were combined with a small portion of meat meal.[173] For pigs or for brood sows it is very important to include alfalfa or other legume hay in the ration, when peas are the supplement to grain.[174] In a Washington trial a ration of barley, wheat, cull peas, 20 per cent dehydrated alfalfa meal, and minerals was as satisfactory for brood sows as one containing fish meal in addition.[175]

In poultry feeding, peas can be used to replace about one-half the animal protein supplements which would be required to balance a ration, but should not be used in such a large proportion as is possible with soybean oil meal.[176] Peas and fish meal make an excellent combination.

When cull peas are considerably lower in price than grain, they are often used to replace part of the grain in rations for dairy cattle, fattening cattle and lambs, or swine. Thus fed, cull peas of a good grade are equal to barley. If ground peas formed more than 40 per cent of the concentrate mixture for fattening calves in a Washington trial, there was serious trouble from bloat when the roughage was sweet clover hay.[177] In other Washington tests pigs on pasture made very satisfactory and economical gains when fed only cull peas and a mineral mixture.[178]

Pea feed, sometimes called pea meal, is the by-product from the manufacture of split peas for human food. It consists chiefly of shrunken, broken, or otherwise damaged peas, together with the pea hulls (or bran) and meal made up of the germs and broken particles from the seed. Pea feed varies considerably in composition. Though it has an average of 23.7 per cent fiber, the fiber seems to be highly digestible, and the content of total digestible nutrients is as high as in pea seed. When fed to dairy cows as part of a suitable concentrate mixture, pea feed has been equal to a mixture of grain, wheat bran, and linseed meal that supplied a similar amount of protein.[179]

856. Velvet beans; velvet bean feed.—Velvet beans are grown chiefly for forage, as has been mentioned in Chapter XVI. When the velvet beans are gathered for feeding to stock, they are generally fed whole in the pod, or else the beans and pods are ground to form *ground velvet bean and pod,* also called *velvet bean feed.*

Velvet beans in the pod contain 18.1 per cent protein and 13.0 per cent fiber, thus being slightly higher in protein but also higher in fiber than wheat bran. They supply slightly less than one-half as much protein as the best grades of cottonseed meal, but furnish as much total digestible nutrients.

Though velvet beans in the pod or the ground beans and pods are not very palatable, they are satisfactory for dairy cows, beef cattle, or sheep when not forming too large a part of the ration. When too much is fed, they may be unduly laxative. The dry beans and pods are satisfactory for fattening cattle, and it does not pay to soak or grind them. However, for dairy cows the value is increased considerably by grinding. If this cannot be done, the beans and pods should be soaked for 24 hours.

With dairy cows the best results are secured when ground velvet beans and pods do not form more than 40 per cent of the concentrate mixture, the rest consisting of better-liked feeds. Thus fed, this feed, on the

average, has been about equal to wheat bran and has been worth about one-half as much as cottonseed meal.[180] Ground velvet bean meal (without the pods) has a somewhat greater value, as it is higher in protein and total digestible nutrients.[181]

Velvet beans in the pod have been satisfactory for fattening cattle, when used as a protein supplement or when fed as the entire concentrate, along with suitable roughage.[182] In the latter case the gains are usually somewhat less than on a combination of corn and cottonseed meal. In 4 Georgia experiments fattening cattle fed 5.2 lbs. a day of velvet beans in the pod, along with broken ear corn in the husk, threshed peanut hay, and minerals, gained slightly more than others fed 2.5 lbs. of cottonseed meal.[183] On the average, the velvet beans in the pod were worth fully as much per ton as cottonseed meal, as they also replaced some corn and hay.

Velvet beans are generally very unsatisfactory for swine (either brood sows or growing and fattening pigs) when forming any considerable part of the ration.[184] This has been the case, no matter whether the beans have been fed shelled, ground, or as ground velvet beans and pods. The velvet beans even cause severe vomiting and diarrhea.

The poor results are caused largely by a substance that is poisonous to swine, and also by the poor quality of the protein in the beans.[185] The toxicity is lessened by cooking and the beans are made more digestible, but this does not generally make them satisfactory. Pigs will not do well when following steers heavily fed on velvet beans, unless they get considerable other feed. When velvet beans do not form more than one-fourth the ration for swine and an efficient protein supplement like tankage or fish meal is included, fair results may be secured.[186] Even velvet bean pasture cannot be recommended for swine.

857. Vetch seed.—The seed from the vetches (*Vicia*, spp.) is similar to pea seed in composition, but vetch seed is sometimes poisonous to stock because of the presence of glucosides from which prussic acid may be formed. (**670**) Danger of poisoning can be avoided by soaking the seed for 24 hours or by steaming it thoroughly.

V. Other Seeds and By-products

858. Coconut oil meal or cake; coconuts.—Coconut oil meal or cake (also called copra oil meal) is the by-product from the production of oil from the dried meats of coconuts, the nuts of the coconut palm (*Cocos nucifera*). Coconut oil meal is made by all the methods—the hydraulic process, the expeller method, and the solvent process.

Coconut oil meal of the usual kind has somewhat less protein than corn gluten feed but more than wheat bran, the average being 21.4 per cent. The protein is of better quality than that in corn gluten feed, but is not of such high quality as that of soybean oil meal. Coconut meal should therefore not be fed as the only protein supplement to grain for swine not on pasture or for poultry. Some such supplement as meat scrap, tankage, or fish meal should be fed in addition.

Coconut meal of the usual kind has an average of 6.7 per cent fat and supplies a trifle more total digestible nutrients than does corn gluten feed. Some of the imported coconut oil meal, coming from small, inefficient oil mills is much higher in fat, averaging 12.0 per cent. Such high-fat coconut oil meal is apt to become rancid if stored too long in warm weather.

Coconut oil meal is fed mostly to dairy cows in this country and is an excellent dairy feed. In a Massachusetts test it was about equal to corn gluten feed, and in an Ohio trial it was fully equal to a mixture of one-half linseed or cottonseed meal and one-half grain.[187] In a Hawaiian experiment 28 per cent of coconut oil meal was a good substitute for part of the soybean oil meal and pineapple bran in a dairy concentrate mixture.[188]

Sometimes the feeding of old-process coconut oil meal may cause a very slight increase in the fat percentage of milk over a considerable period. (**1064**) A limited amount of coconut meal produces firm butter of excellent quality, but over 3 to 4 lbs. per head daily may make the butter too hard.

Coconut oil meal is also satisfactory as a protein supplement for fattening cattle or lambs.[189] For swine feeding, coconut oil meal may be used in place of such feeds as wheat middlings or linseed

meal.[190] Like these feeds, it does not generally produce good results when fed to young pigs not on pasture as the only supplement to grain.

Limited amounts of coconut oil meal can be included in poultry rations when sufficient protein of better quality is provided.[191] On the Pacific Coast 2.5 to 5.0 per cent of coconut meal is sometimes used in poultry mashes. In an English test 20 to 25 per cent of coconut meal was satisfactory as a substitute for wheat bran in the mash for laying hens.[192] On the other hand, in Philippine tests coconut oil meal did not give good results in rations for chicks and ducklings.[193]

If coconut oil meal is cheaper in price than grain it may be used as a substitute for part of the grain in feeding cattle, sheep, horses, or swine, being worth about as much per 100 lbs. as ground barley.[194] In Ohio tests coconut oil meal was worth more than corn when forming one-fourth of the ration for pigs, but it was worth only 88 per cent as much as corn when forming 40 per cent of the ration.[195]

Coconut oil meal of a good grade should be whitish or very light brown in color. Too high a temperature in the process of expressing the oil will result in a dark oil meal which has a lower value, because the digestibility is decreased considerably.

Coconut meal has a high capacity for absorbing molasses and is sometimes used for this purpose in mixed feeds. "Candied copra," a mixture of coconut oil meal with a considerable proportion of cane molasses, usually has only 11 to 14 per cent protein.

Coconuts were used successfully in Guam tests for feeding growing pigs and brood sows on pasture.[196] As the coconut meats contain 60 to 70 per cent fat, on the dry basis, the energy value is correspondingly high.

859. Acorns.—In some regions acorns, the nuts of various species of oak (*Quercus*, spp.), are of importance in swine feeding, the pigs usually being allowed to forage upon the scattered nuts. In an English test pigs made satisfactory gains when fed acorns and only a limited amount of concentrate mixture.[197] It required 174 lbs. of dried acorns to replace 100 lbs. of the concentrate mixture in feeding value.

Acorns may be used for other stock in limited amounts, but poisoning has been reported where stock ate damaged acorns or too large amounts.[198] Statements have been made that acorns tend to dry up cows, if a considerable amount is eaten. This may be due to the high content of tannin. In certain range districts of California, deformed calves, which are called "acorn calves," are sometimes produced by range cows. Investigations have shown that this trouble may occur where the cows eat no acorns, but are forced to live on weathered, mature range forage for a long time. (192)

In tests by the United States Department of Agriculture, the feeding to hens of rations containing 25 to 50 per cent of acorn meats, or 25 per cent of whole acorns or acorn hulls, produced eggs with olive-colored yolks, and the hatchability was decreased.[199]

860. Adlay, or Job's tears.—Adlay, or Job's tears (*Coix Lacryma-Jobi*), a relative of the common cereals, has been cultivated since ancient times in Asiatic countries. The seeds of hard-hulled varieties are used as beads, and soft-hulled varieties are used for food. In tests in Brazil the yields of adlay seed were promising, in comparison with the common cereals.[200] The whole seed was used satisfactorily in rations for chickens and hogs.

861. Almond hulls.—Almond hulls are a by-product of the almond industry. The hull of the almond (*Prunus amygdalus*) is comparable to the fleshy portion of the peach, which is a close relative. When the almonds ripen, the hulls usually crack and open. After being harvested the nuts are removed from the attached hulls by a machine.

Until recently, most of California's almond-hull production was burned or used for livestock bedding. California experiments show that the dried and ground hulls can be used as a substitute for part of the grain for feeding ruminants.[201] The dried hulls contained 18 to 31 per cent sugar and only 10 to 17 per cent fiber, with a total digestible nutrient content of 53 to 72 per cent. Hulls from varieties with thick, fleshy hulls have the greatest feeding value.

862. Babassu oil meal.—Babassu oil meal is produced from the hard-shelled seed of a Brazilian palm (*Orbignya speciosa*). It is similar in appearance and composition to coconut oil meal, averaging a trifle higher

in protein. It is palatable to stock and in a Danish trial was about equal to coconut meal and in a New Jersey trial to corn gluten feed for dairy cows.[202] Like palm-kernel oil meal, it seems to cause a slight increase in the fat percentage in milk. In a California test with chicks, babassu oil meal satisfactorily replaced part of the grain, when not forming more than 10 per cent of the ration.[203]

863. Castor beans.—Castor beans (*Ricinus communis*) and the oil meal from processing them for castor oil are very toxic to stock. Studies are being conducted to develop a practical method of treating the oil meal to make it safe for feeding.[204]

864. Cocoa meal; cocoa shells; cocoa pods.—In the manufacture of chocolate and cocoa from the beans of the cacao tree (*Theobroma cacao*), the beans are first roasted and the cocoa shells, which form about 12 per cent of the weight, are removed. The beans are then ground very finely, and a portion of the semi-liquid mass is pressed to remove part of the fat, which is called cocoa butter. The residue, after hardening and being ground, forms the cocoa that is used as a beverage. Chocolate is made by enriching the ground beans with a certain percentage of cocoa butter.

On account of the large demand for chocolate in confections and other food, more cocoa must often be produced than can be sold for human use. This may then be offered for sale as a stock feed under the name of *cocoa meal*. Cocoa meal has an exceedingly low feeding value. Still more important, when it forms any appreciable part of the ration it is definitely poisonous, because of the alkaloids (theobromine and caffeine) which it contains. These alkaloids have a cumulative effect on animals.

Extensive experiments have been conducted to find whether or not cocoa meal can be safely fed to stock.[205] These experiments have shown that it is injurious or even disastrous to pigs and poultry when forming as little as 7.5 to 10 per cent of the ration. A mixture containing 15 per cent was unpalatable to stock, caused scours in calves, and decreased the milk yield of cows. Cocoa meal also has a very low digestibility and tends to depress the digestibility of the other feeds in the ration. Solvent-process cocoa meal has somewhat less alkaloids, but in English tests it was disliked intensely by pigs, poultry, and sheep.

Because of these results, even when cocoa meal is seemingly cheap in price, it should not be fed to stock, except perhaps to adult cattle in very small amounts in times of great feed shortage. In Great Britain during World War II the use of cocoa meal in mixed feeds was permitted only in feeds for adult cattle and to the extent of 2.5 per cent of the mixed feed.

Cocoa shells consist of the hard outside coating of the cocoa bean. These shells, which are dark brown and brittle, are used in a few mixed feeds. Only 27 per cent of the crude protein in this material is digestible, on the average. The shells from sun-cured cocoa beans have a considerable content of vitamin D.

In tests at the Massachusetts Station cocoa shells were worth not more than half as much as corn meal.[206] Woodman of England advises that cocoa shells be fed only to mature cattle and in amounts no greater than 2 lbs. per head daily, because cocoa shells contain small amounts of the alkaloids which make cocoa meal dangerous.[207] He concludes that cocoa shells when thus fed have no higher feeding value per pound than a good roughage.

Cocoa pods resemble grass hay in protein and fiber content, but in Costa Rica trials their feeding value for dairy cows was higher than would be expected from the chemical composition.[208] When ground, dried cocoa pods replaced ground corn in the ration, the milk production was just as high. In view of the chemical composition of cocoa pods, further trials would be needed to conclude that they equal corn in feeding value.

865. Coffee bean pulp.—Coffee bean pulp, the fleshy covering of coffee beans (*Coffea arabica*), has mostly been a waste by-product in coffee-growing countries. Experiments in El Salvador show, however, that it is nearly as digestible as corn grain and can be substituted for corn in a dairy ration.[209] It is not palatable when fed alone, but is readily eaten when mixed with molasses.

866. Hemp-seed oil meal.—Hemp-seed oil meal is the by-product in producing oil from the seed of hemp (*Cannabis sativa*). It contains 31 per cent protein, but it is high in fiber and furnishes less total digestible nutrients than good legume hay. In California tests hemp-seed oil meal was not palatable to stock.[210] It should therefore be mixed with better-liked feeds.

German authorities state that hemp-seed oil meal may contain narcotic substances which have injurious effects on stock when any large amount is fed. They recommend that dairy cows not be fed more than 1.1

lbs. of hemp-seed oil meal per head daily; horses and beef cattle not more than 3 lbs. per head daily; and sheep not more than 0.25 lb. per head daily. Hemp-seed oil meal is satisfactory in poultry rations when forming 2.5 to 5 per cent of the mash.[211]

867. **Ivory nut meal.**—Ivory nuts, or vegetable ivory, the nuts of the ivory palm (*Phytelephas macrocarpa*), are manufactured into buttons and the residue is ground finely to form ivory-nut meal. This consists chiefly of mannan, one of the less common carbohydrates. In studies at the Massachusetts Station this material was found to be fairly digestible.[212] It supplies about as much total digestible nutrients as barley grain, but contains only 0.8 per cent digestible protein.

868. **Kapok oil meal.**—Kapok oil meal is the by-product from the manufacture of oil from the seed of the kapok tree (*Ceiba pentandra*). Kapok fiber adheres to the seed of this tree in a manner somewhat similar to that found in the cotton plant. Kapok oil meal was so unpalatable to sheep in a California trial that the digestibility of the feed could not be determined.[210] When used for pigs as one-third of the protein supplemental mixture, along with tankage and alfalfa hay, kapok oil meal gave satisfactory results in Oregon tests.[213] It tended to produce hard pork.

869. **Mustard-seed oil meal.**—Mustard-seed oil meal, the by-product in producing mustard oil from various species of mustard seed (*Brassica,* spp.), can be used as a partial substitute for other oil meals in stock feeding. In Kansas and Montana trials mustard-seed oil meal was a satisfactory substitute for cottonseed meal or soybean oil meal for young beef or dairy cattle.[214] In Kansas trials it gave good results when forming not over half the protein supplement for pigs.[215] In another test 9 per cent was satisfactory as a substitute for part of the meat meal in a chick starter.[216]

870. **Palm-kernel oil meal or cake.**—The usual kind of palm-kernel oil meal or cake is the by-product from the production of oil from the seed kernels of certain tropical oil palms (*Elaeis,* spp.). It varies considerably in composition, especially in fiber content. The usual grade has slightly more protein than does wheat bran and supplies somewhat more total digestible nutrients.

Opinions differ with reference to the palatability of palm-kernel oil meal or cake. Woodman states that in England it is considered rather unpalatable, especially the solvent-process oil cake.[217] It should therefore be mixed with well-liked feeds and stock should be accustomed to it gradually. Palm-kernel oil meal or cake has been used chiefly in Europe, where it is mostly fed to dairy cows. Solvent-process palm-kernel oil meal was about equal to wheat bran for dairy cows in a Kentucky test, when used as a partial substitute for it.[218] Old-process palm-kernel meal may cause a temporary increase in the fat content of the milk and perhaps a very slight increase over a longer period. (**1064**)

Palm-kernel oil meal tends to produce hard fat when fed to stock, and thus makes firm butter and pork of good quality. It is not very palatable to pigs and should not form more than about one-fifth of their ration. Palm-kernel meal was a satisfactory substitute for wheat middlings in an English trial with laying hens.[219]

Oil meal is also made from the seed of the corozo palms (*Orbignya cohune* and *Scheelea,* spp.). In experiments in Guatemala this oil meal was found to be very palatable to stock.[220] It gave good results as the chief protein supplement for pigs and was a satisfactory substitute in rations for chicks when furnishing not more than half the protein.

871. **Perilla oil meal.**—This is the by-product from the production of oil from the seed of perilla plants (*Perilla,* spp.), Chinese plants which are members of the mint family. It contains an average of 38.4 per cent protein, but is high in fiber, having 20.9 per cent. In digestion trials at the California Station perilla oil meal was palatable to sheep. The protein and fat were well digested, but the fiber and the nitrogen-free extract poorly digested, and the feed had only 62 per cent total digestible nutrients.[210]

872. **Poppy-seed oil meal.**—This oil meal, which rarely appears on American markets, is the by-product from the production of oil from the seed of the opium poppy (*Papaver somniferum*). It contains about 36 per cent protein. Since it has weak narcotic properties, because of the presence of opium alkaloids, it is not generally fed to young animals or to breeding stock. The amount for dairy cows should be limited to 2 or 3 lbs. per head daily, since a greater amount is said to decrease the fat percentage of the milk.

873. **Rape-seed oil meal.**—Rape-seed oil meal, or colza oil meal, is the by-product from the production of oil from various kinds of rape seed (*Brassica,* spp.). It contains an average of 33.5 per cent protein, 8.1 per cent fat, and 10.8 per cent fiber.

Experience in Germany, where it has long been used for stock, shows that it must be fed very carefully to avoid injurious results.

Rape-seed oil meal contains varying amounts of glucosides, from which mustard oils may be formed in the digestive tracts of animals under certain conditions. The mustard oils are irritating to the digestive system and produce serious results when present in appreciable amounts. Also, rape-seed oil meal tends to produce goiter, especially in poultry, if fed in too large amounts.[221] This goitrogenic effect can be avoided by adding potassium iodide to the ration or by extracting the rape-seed meal with hot water.

To avoid bad results, it is best to feed no more than 2 lbs. per head daily to cattle and corresponding amounts to other stock. Not over 10 per cent should be included in a ration for laying hens and not over 5 per cent for chicks.[222] Caution is especially necessary in feeding rape-seed oil meal to young animals or to those which are pregnant. However, rape-seed oil meal, fed at the rate of 0.5 lb. per head daily to pregnant ewes being wintered, equalled linseed meal in a Canadian trial.[223]

On account of its sharp, bitter taste, rape-seed oil meal is often not liked by stock, especially at first. It should therefore be mixed with better-liked feeds.

874. Rubber-seed meal.—This by-product (also called Para rubber meal) from the manufacture of oil from the seed of the Para rubber tree (*Hevea brasiliensis*) is occasionally found on the United States markets. Rubber-seed meal is a dry, rather powdery meal which is not very palatable when fed alone. It should therefore be mixed with well-liked feeds. In a Virginia trial cows were fed 5 lbs. per head daily of either rubber-seed meal or linseed meal, with alfalfa hay and corn silage.[224] The rubber-seed meal gave as good results as the linseed meal in this ration, which supplied somewhat more protein than was required by the cows. In tests in England it was fed satisfactorily to milk cows and fattening cattle, but a few sheep refused to eat it, even when mixed with other feeds.[225]

875. Safflower oil meal or cake.—Safflower (*Carthamus tinctorius*) has long been cultivated in India and Egypt as an oilseed crop and a source of a red dye obtained from the flowers. It has recently been grown to some extent as an oil-seed crop in some of the western states.

Safflower seed of improved varieties has 29 to 36 per cent of oil, but has 40 per cent or more of hulls, which have very little feeding value. It is difficult to remove the hulls completely in oil-milling, and much safflower-seed oil meal is made from unhulled seed. Such oil meal has only about 18 to 21 per cent protein and contains 30 per cent fiber or more, as much or more than in hay. By improved methods, oil meal can now be made that has as much as 40 per cent protein and less than 10 per cent fiber. Safflower-seed oil meal is rather low in the essential amino acids lysine and methionine.[226] For poultry or swine these lacks are made good by fish meal.

Experiments have shown that safflower-seed oil meal from well-hulled seed is about equal to linseed meal or soybean oil meal as a protein supplement for dairy cows, beef cattle, or sheep.[227] On the other hand, it will require about 200 lbs. of safflower-seed oil meal from unhulled seed to equal 100 lbs. of the high-protein oil meals. Safflower-seed oil meal is too high in fiber to be useful in rations for chicks, but that low in hulls is satisfactory as a substitute for soybean oil meal for laying hens.[228]

876. Sesame oil meal or cake.—This protein-rich oil meal or cake is the by-product in the production of oil from sesame seed (*Sesamum*, spp.) which has been long produced in the Orient. The seeds of most varieties of sesame, or benne, shatter badly as they ripen, necessitating hand harvesting. Recently, non-shattering varieties have been developed, which can be harvested with a grain combine. These are attracting interest in some of our states, especially in Texas.

Sesame oil meal contains about as much protein as cottonseed meal, averaging 43.3 per cent. It is also high in calcium and phosphorus. It is well-liked by stock, keeps well in storage, and is satisfactory for all classes of stock. If it forms too large a part of the ration, it produces soft pork and butter.

Sesame oil meal is rather low in lysine and therefore should not be used as the only protein supplement for poultry or swine, but should be combined with such a supplement as meat scrap, fish meal, or soybean oil meal, which are rich in lysine.[229] It is an excellent protein supplement for dairy cattle, beef cattle, or sheep, and also for poultry or swine when fed with a lysine-rich supplement.[230]

877. Screenings; weed seeds.—When wheat and the other small grains come from the threshing machine or combine harvester, they contain various amounts of screenings. These must be removed as completely as

possible before the grain is milled for human food. The screenings consist of small, broken, or shrunken kernels of grain, wild oats and wild buckwheat, smaller weed seeds, and more or less chaff and broken pieces of stem.

When farmers market wheat or other grain before first cleaning it thoroughly, they not only lose the feeding value of the screenings, but they also have to take a lower price for the grain. The increase in price will much more than cover the cost of cleaning the grain, and in addition the screenings will be saved for feeding on the farm.

The best grades of screenings, consisting chiefly of broken and shrunken kernels of grain, with wild oats and other palatable weed seeds, resemble oats in composition. Such screenings, when ground, may nearly equal grain in feeding value.[231] Light, chaffy screenings are much higher in fiber and consequently lower in value. Some poor-quality screenings resemble straw more than grain in composition and value.

If the screenings contain too large a proportion of "black seeds" consisting of mustard seed, lamb's quarters, and pig weed, the value is low. In case there is much mustard seed present, the screenings may be very unpalatable to stock. Screenings containing a large proportion of certain weed seeds may even cause an objectionable flavor in the meat of animals heavily fed on them.[232] Poisonous seeds, such as corn cockle, are rarely present in sufficient amounts in screenings to cause bad effects. Flax screenings are usually considerably higher in fat than wheat screenings, due to immature or broken flax seeds. However, they are also generally higher in fiber.

In Canada recleaned wheat screenings are classified in definite grades under the Grain Inspection Act. No. 1 screenings must not contain more than a total of 6 per cent of weed seeds and No. 2 screenings not over 10 per cent. Either grade must not contain a sufficient proportion of injurious weed seeds to harm stock. The material removed in recleaning screenings is sold as "refuse screenings."

Unless the weed seeds in screenings are killed by very fine grinding, many will pass through stock uninjured and be carried to the fields in the manure. Therefore, screenings should be finely ground, even for sheep.

Tests at the Massachusetts Station showed that screenings ground in a hammer mill with sharp knives and four-sixtyfourths inch screens had very few viable weed seeds.[233] If the screenings had an unusual number of smaller noxious weed seeds, it was necessary to use three-sixtyfourths inch screens.

According to the official definition of the Association of American Feed Control Officials, *grain screenings* should consist of 70 per cent or more of grain (light and broken), including wild buckwheat and wild oats, should have not more than 6.5 per cent ash, and should not contain more than 4 whole primary noxious weed seeds per pound and not more than 100 secondary noxious weed seeds per pound.[4] *Mixed screenings,* to be labeled as mixed screenings (grains, seeds, hulls, chaff), are screenings not conforming to this definition. They should not contain more than 27 per cent fiber. If they have more than 13 per cent ash, the words "sand" and "dirt" must be included in the list of ingredients. *Chaff and/or dust* is the other material separated from grains or seeds in the usual commercial cleaning processes. If it contains more than 15 per cent ash, the words "sand" and "dirt" must appear on the label.

Ground screenings of good quality can be used satisfactorily as one-fourth or somewhat more of the concentrate mixture for dairy cows, beef cattle, or swine. The best results are secured when screenings are fed with considerable legume hay. Screenings are fed extensively to fattening lambs, especially in the wheat-growing areas of the West. Often they are used as the only concentrate. At the start light-weight, chaffy screenings are fed, and when the lambs are safely on full feed, heavier screenings, richer in grain, are substituted. In a Canadian trial No. 1 ground recleaned feed screenings were a satisfactory substitute for one-third of the corn in a broiler ration.[234] A larger proportion of screenings reduced the gains and feed efficiency. Various proportions of screenings are used in certain of the lower-grade mixed feeds, especially those for dairy cows.

The composition and value of alfalfa-seed screenings and other legume-seed screenings have been discussed earlier in this chapter. (**850**)

Cheat seed (*Bromus secalinus*), or chess, which is a common weed in grain fields, resembles oats in composition. Ground cheat was about equal to ground barley for dairy cows in Maryland trials, when forming 30 per cent of the concentrate mixture.[235] It is of interest that cheat, grown as a crop, produced more pounds of seed per acre than oats.

In Montana tests dairy cows ate concentrate mixtures readily which contained 10 per cent of *wild mustard seed* or 8 per cent of *fanweed seed*.[236] The milk yield was as high as on a normal mixture and the flavor of the milk was not injured.

878. Sunflower seed; sunflower seed oil meal.—In some countries, as in Argentina and Russia, sunflowers are an important crop for oil production. Also, the hulled seeds are used for human food. Recently, considerable acreages of low-growing varieties of sunflowers have been grown in western Canada for oil processing, and there has been some interest in sunflowers for oil production in this country. The use of sunflowers for forage has been discussed in Chapter XIX.

Only a very small amount of sunflower seed is raised here for feed, because other crops produce much larger yields of feed per acre. A small amount of sunflower seed (usually not more than 1 or 2 per cent) is often included in commercial mixed scratch grains for poultry, because of the distinctive and attractive appearance of the seeds.

Sunflower-seed oil meal or cake, made from thoroughly-hulled seed is even higher than soybean oil meal in protein, but that made from unhulled seed has only 20 per cent protein, or even less. Sunflower-seed oil cake is well-liked by stock and keeps well in storage. It is popular in Europe for all classes of stock, especially dairy cows.[237] It is said to resemble linseed meal in its favorable effect. Because of the character of the oil it contains, hydraulic-process or expeller-process sunflower-seed meal or cake tends to produce soft pork, and it also makes the butter soft, if fed in large amounts to dairy cows.

Sunflower-seed oil meal should not be used as the only protein supplement for poultry or swine, because the protein is rather low in lysine.[238] Over-heated sunflower-seed oil meal is especially deficient in lysine, which is destroyed by undue heat. Sunflower-seed oil meal should be combined with such a supplement as meat scrap or fish meal, which are rich in lysine. In swine or poultry rations it can partially replace soybean oil meal.

In Florida experiments sunflower-seed oil meal was fully equal to cottonseed meal as the protein supplement for fattening steers, but was decidedly inferior to soybean oil meal or peanut oil meal as the only protein supplement to corn and alfalfa meal for pigs.[239] In an Illinois test a combination of sunflower-seed oil meal, soybean oil meal, and alfalfa meal, was a good supplement to corn for pigs.[240]

QUESTIONS

1. Discuss the composition and nutritive value of soybeans.
2. For what classes of stock does cooking greatly increase the value of soybeans?
3. Describe the three oil-milling methods.
4. Why is soybean oil meal a popular feed?
5. What is soybean mill feed?
6. Discuss the use of soybeans for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry.
7. Compare the value of soybean oil meal and soybeans for each of the above classes of stock.
8. Discuss the composition and nutritive value of cottonseed meal. To what classes of stock should cottonseed meal be fed only in strictly limited amounts? Why?
9. Compare the value of cottonseed meal and of soybean oil meal or linseed meal for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry.
10. If the following are important in your district, discuss the composition and value: (a) Cottonseed feed; (b) whole-pressed cottonseed; (c) cottonseed.
11. Discuss the composition of cottonseed hulls and their value for: (a) Dairy cattle, (b) beef cattle, (c) sheep.
12. Why is not flaxseed commonly used as a feed?
13. Discuss the composition and nutritive value of linseed meal.
14. What is the value of linseed meal in comparison with other protein supplements for: (a) Dairy cattle; (b) beef cattle; (c) sheep; (d) horses and mules; (e) swine; (f) poultry?
15. How are peanuts used for stock feeding?
16. Discuss the composition and value of: (a) Peanut oil meal; (b) unhulled peanut oil feed; (c) peanut skins; (d) peanut hulls.
17. Discuss the composition and use of any of the following that are of importance in your district: (a) Cull beans; (b) cowpeas; (c) lespedeza seed; (d) peas; (e) pea feed; (f) velvet beans.
18. Compare the composition and feeding

value of coconut oil meal and corn gluten feed.

19. Discuss the composition and use of any of the following that are fed to livestock in your section: (a) Acorns; (b) babassu oil meal; (c) palm-kernel oil meal; (d) rape-seed oil meal; (e) safflower oil meal; (f) sesame oil meal; (g) screenings; (h) sunflower seed; (i) sunflower seed oil meal.

CHAPTER XXIII

MISCELLANEOUS CONCENTRATES

I. Cow's Milk and Milk By-products

879. Nutritive value of milk.—Whole milk is nearly a perfect food for young mammals. The great nutritive merits of milk have been considered in detail in Chapter IX, as well as the deficiencies that develop when milk is fed to young animals as the only food for an unnaturally long time. (269) The effects of various factors upon the composition and nutritive value of milk are discussed in detail in Chapters X and XXV.

Dairy Calves Need Milk
It is difficult to raise thrifty dairy calves unless they get a good start on milk.

It is important to note that pasteurization does not decrease the value of whole milk or of skimmilk, buttermilk, or whey for feeding dairy calves or other farm animals.[1]

880. Whole milk.—Whole cow's milk is too valuable for human food to be fed to livestock under usual conditions, except in the case of young dairy calves until they become old enough to live on other feeds. The use of whole milk for this purpose is discussed fully in Chapter XXVII. It is not necessary to continue the feeding of whole milk to calves longer than 2 to 4 weeks, if a plentiful supply of skimmilk is available or if reconstituted skimmilk (made from dried skimmilk) or an efficient milk replacer is fed. When other methods are followed, whole milk should generally be fed for a longer period.

One should not hesitate to use whole milk when needed in rearing an orphan foal or lamb, and young stock being fitted for show can be forced ahead rapidly by its judicious use. Milk moderate in fat content gives better results with young calves or pigs than milk very high in fat. (269)

Whole milk has about 3 per cent or more of casein, 0.5 per cent albumin, and traces of other proteins. It contains from 4.8 to 5.0 per cent of milk sugar, which is shown in feeding stuff analyses as nitrogen-free extract. Milk sugar is only slightly sweet, is much less soluble than cane sugar, and has about the same feeding value as starch. When milk sours, some of the sugar is changed to lactic acid, which curdles the casein. This fermentation ceases when about 0.8 per cent of acid has developed, so that in sour milk usually most of the sugar is still unchanged.

It is shown in Chapter XXV that the percentage of fat varies widely, depending on individuality, breed of cow, and the portion of the milk drawn. The strippings sometimes contain 10 times as much fat as the first-drawn milk.

Whole milk contains both vitamin A and carotene. The relative proportions of these depend on the breed of cow, as is pointed out in Chapter XXV. (1043)

881. Skimmilk.—Because of the removal of most of the fat, skimmilk is slightly higher than whole milk in content of protein, milk sugar, and minerals.

Skimmilk from properly-adjusted centrifugal separators has only 0.03 to 0.10 per cent fat.

Because of the low fat content, skimmilk supplies but little vitamin A value, since nearly all the vitamin A and carotene in milk are contained in the fat. Skimmilk also furnishes considerably less energy than whole milk per 100 lbs. because of the removal of the energy-rich fat. Skimmilk is rich in riboflavin and is a good source of vitamin B_{12} and other B-complex vitamins.

In feeding skimmilk, it should be borne in mind that it is very high in protein, on the dry matter basis. Because of this, there is no need of having other protein supplements in the ration when sufficient skimmilk is used. Instead, to secure the maximum value from skimmilk, it should be fed with cereal grain or other concentrates low in protein.

Skimmilk is used chiefly for dairy calves, pigs, and poultry. When fed in suitable amounts to these classes of stock, it has a considerably higher value per 100 lbs. than an equal amount of nutrients in the feeds from other animal sources, such as tankage, meat scrap, or fish meal. Skimmilk and other dairy by-products have an especially high value for poultry, largely because of their richness in riboflavin. Since skimmilk lacks vitamin A, it is highly important that the ration include other feeds which furnish plenty of vitamin A value.

Full information on the use of skimmilk in raising dairy calves is given in Chapter XXVII. It is there shown that just as thrifty calves can be raised when they are changed entirely from whole milk to skimmilk by 3 to 6 weeks of age, as when whole milk is continued longer. The use of skimmilk for swine and poultry is discussed in later paragraphs. (884–887)

If more skimmilk is available than can be used for calves, pigs, and poultry, it may be fed to dairy cows and heifers. Only a few cows will drink skimmilk, but it may be poured on the concentrate mixture in a pail, and this mixture then fed on top of the silage. In Minnesota trials 8 lbs. of skimmilk replaced 1 lb. of linseed meal when dairy cows were thus fed 2 lbs. of skimmilk per pound of grain mixture, and the value of skimmilk for dairy heifers was similar.[2] Skimmilk did not have quite as great a value as this for dairy cows in tests by the United States Department of Agriculture.[3]

882. Importance of pasteurizing factory by-products.—Farmers should insist that skimmilk, buttermilk, or whey be thoroughly pasteurized or sterilized at the factory to kill all disease-producing bacteria, before they take it back to the farm for feeding. Otherwise, bovine tuberculosis, brucellosis, or other diseases may be widely spread from a diseased herd. The pasteurized product also keeps better and is less likely to cause scours. Pasteurization is likewise advantageous to the factories, for the milk cans may be more readily kept in good condition and the quality of the milk delivered at the factory will thus be improved.

883. Buttermilk.—Unless wash water from the churn has been added, buttermilk has practically the same composition as skimmilk, except that it usually contains 0.4 per cent or more of fat. Also, in buttermilk from sour cream a part of the sugar has been changed to lactic acid. Buttermilk of good quality is a satisfactory substitute for skimmilk in feeding calves, pigs, and poultry, undiluted buttermilk being worth about as much as skimmilk.

Since buttermilk often has a more laxative effect than skimmilk, calves should not be changed to it quite so early as in the case of skimmilk. Buttermilk that is allowed to ferment and putrefy in dirty tanks is a dangerous feed.

884. Skimmilk and buttermilk for swine.—Because of the richness in excellent-quality protein, either skimmilk or buttermilk is an ideal protein supplement for all swine. When either skimmilk or buttermilk is used as the supplement to grain for pigs, the gains will generally be slightly more rapid than when tankage or fish meal is used as the

only supplement. These feeds are of especially high value for young pigs before weaning and also for several weeks after weaning.

It must be borne in mind that skimmilk, buttermilk, and whey are all very low in vitamin A value and that they have practically no vitamin D. For all swine not on pasture, good legume hay should therefore be fed, if possible, in addition to grain and these dairy by-products. Legume hay is especially necessary when little or no yellow corn is fed, and also for young pigs during winter when they are not protected against rickets by abundant exposure to sunlight.

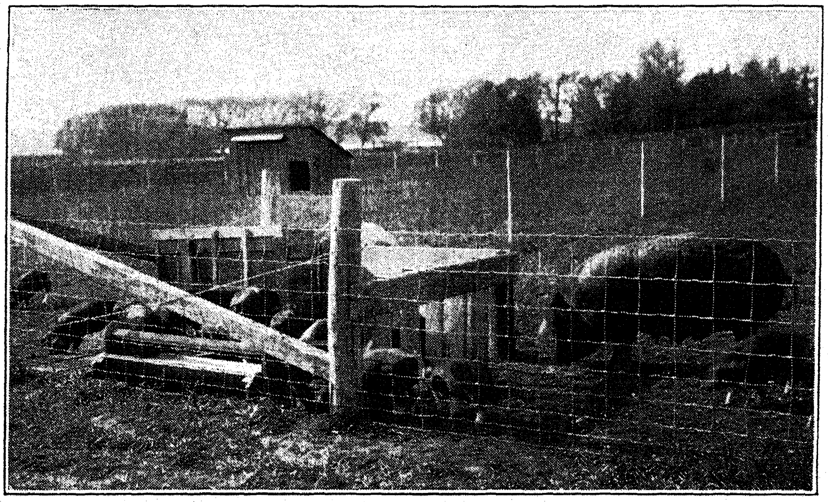
For pigs before and soon after weaning, skimmilk is best if fed fresh. If sour milk is used, it should always be fed sour, and not sweet at one feeding and sour at the next. To prevent the introduction of disease, dairy by-products should be pasteurized at the creamery or cheese factory before being returned to the farm.

Numerous experiments have shown that buttermilk which has not been diluted by the addition of churn washings has about the same value as skimmilk for swine.[4] Storage of buttermilk for a few days under sanitary conditions does not injure its value.[5]

The feeding of skimmilk, buttermilk, or whey to pigs helps to reduce infection with roundworms and other intestinal worms.[6]

885. Amount of skimmilk or buttermilk to feed swine.—Skimmilk and buttermilk are too rich in protein and also too watery to produce economical gains when fed alone. They should therefore always be fed with grain or other carbohydrate-rich concentrates. These dairy by-products have the greatest value when no more is used than will balance the ration. Much larger amounts can, however, be fed to swine when a surplus is available, after the dairy calves and poultry have had sufficient.

The additional skimmilk or buttermilk that may be used beyond the amount needed to balance the ration will, of course, be worth much less per pound than the portion that is actually needed as a protein supplement. This is be-



Skimmilk Is an Excellent Feed for Pigs and Calves

Rich in protein of the highest quality and high in calcium and phosphorus, skimmilk is a superior feed for young animals. These young pigs are being fed skimmilk and a suitable concentrate mixture inside the "creep," where the sows cannot enter. (From Wisconsin Station.)

cause the pigs will be able to use the excess skimmilk only as a source of energy and not as a high-quality protein supplement.

The lessened value of skimmilk or buttermilk when more is fed than needed is well shown by 2 Ohio tests.[7] Young pigs were fed until they were ready for market on various proportions of skimmilk and corn, in comparison with others fed corn and tankage. When 1 lb. of skimmilk was fed with each pound of corn, skimmilk was worth 51 cents per 100 lbs., but when 3 lbs. of skimmilk were fed per pound of corn, the value was reduced to 30 cents. When the pigs were allowed to drink all the skimmilk they would take in addition to a full feed of corn, each 100 lbs. of the skimmilk was worth only 21 cents.

Because of the high efficiency of milk protein as a supplement to the cereal grains, pigs fed grain and either skimmilk or buttermilk do not require quite as much protein as is advised in the feeding standards.

The proportion of skimmilk or buttermilk that is needed to balance corn or other grain will depend on the age of the pigs. Just after weaning, pigs require so much protein that 4 to 6 lbs. of skimmilk or buttermilk are needed to balance each pound of corn. This is a larger proportion of milk than pigs will usually take when they are full-fed on corn. Therefore, milk should preferably be used at this time in combination with a limited amount of other protein supplements. An excellent combination is corn, skimmilk, and a small amount of wheat middlings or linseed meal (with legume hay in addition for pigs not on pasture).

As the pigs grow older, the proportion of skimmilk or buttermilk needed to balance the ration decreases as follows: Pigs weighing 50 to 100 lbs., 2.5 to 3 lbs. milk to 1 lb. corn; pigs weighing 100 to 150 lbs., 2 to 2.5 lbs. milk to 1 lb. corn; pigs weighing 150 to 200 lbs., 1.5 to 2.0 lbs. per pound of corn; and pigs weighing over 200 lbs. only 1.0 to 1.5 lbs. of milk for each pound of corn. Where barley or wheat is fed in place of corn, only about one-half to two-thirds as much milk is needed for each pound of grain as with corn. Pigs fed corn on good pasture will need only about one-half as much milk for each pound of grain.

If the above amounts of milk are available, there is no need of adding any other protein-rich feed. Adding a protein supplement like tankage to a ration of grain and plenty of skimmilk may increase the rate of gain of pigs a trifle, but the use of the tankage will be uneconomical.[8] On the other hand, if there is not quite enough skimmilk to balance the ration, then it will pay to feed a small amount of some other supplement, like tankage, linseed meal, or wheat middlings.

As the pigs grow older, the proportion of skimmilk or buttermilk needed to balance the ration decreases, but the pigs eat more grain per head daily. Therefore, after pigs reach a weight of 40 to 50 lbs., the weight of milk that is needed per head daily to balance the ration remains about constant. For pigs not on pasture that are full-fed corn and supplied with legume hay in addition, 6 lbs. of skimmilk or buttermilk per head daily will produce rapid and economical gains.[9] The rate of gain may be a trifle more rapid when more is fed, but generally the value of the milk per 100 lbs. will be less.

For pigs full-fed corn on good pasture, a daily allowance of only 3 to 4 lbs. of milk per head is satisfactory.[10] If an abundance of milk is available, the gains can be increased slightly by feeding 4 to 6 lbs. of milk a day, but the milk will then have a lower value per 100 lbs.

When there is a surplus of skimmilk or buttermilk that cannot be utilized by other stock, it does no harm to let swine have a large amount of milk, even all they will drink. In Wisconsin trials young sows allowed 20 to 30 lbs. of skimmilk per head daily during pregnancy had excellent litters.[11] Their pigs were larger and more vigorous than those from sows fed tankage as the protein supplement.

886. Money value of skimmilk or buttermilk for swine.—The value of skimmilk as a protein supplement for swine has been determined in numerous experiments, by comparing a ration of corn and skimmilk with a ration of corn and tankage or some other efficient supplement. To make the comparison reliable, just enough of skimmilk and of the other supplement must be fed to balance the ration properly.

In 12 such experiments pigs not on pasture have been fed corn (usually yellow corn) and skimmilk in comparison with others fed corn and tankage from a weight of about 75 lbs. until ready for market.[12] The pigs fed skimmilk and corn gained 1.36 lbs. a day, on the average, in comparison with 1.24 lbs. for those fed tankage. In these trials each 100 lbs. of skimmilk saved 7.3 lbs. tankage, plus 10.9 lbs., corn, without giving any credit for the more rapid gains produced by feeding skimmilk. The high value of the dry matter in skimmilk is shown by the fact that 100 lbs. of skimmilk, containing only 9.5 lbs. dry matter, replaced 15.7 lbs. of dry matter in corn and tankage.

For young pigs not on pasture, neither corn and skimmilk nor corn and tankage is an ideal ration. These rations can both be improved by adding a small amount of good legume hay. It is therefore important to know the value of skimmilk when it is compared with tankage in an ideal dry-lot ration which includes legume hay. In 6 such experiments fully as good a showing was made by skimmilk as in the experiments mentioned previously.[13] When skimmilk was tested in this critical way, the gains of the pigs fed skimmilk were a trifle more rapid than of those fed tankage. Each 100 lbs. of skimmilk was equal to 7.0 lbs. of tankage plus 11.7 lbs. corn or equivalent.

These 6 trials give the best measure of the value of skimmilk or buttermilk per 100 lbs. when just about enough is fed to balance a ration. From these figures the money value of these dairy by-products under local conditions can readily be found. For example, with tankage at $100 a ton and corn at $1.40 per bushel ($50 a ton), skimmilk or buttermilk is worth about 64 cents per 100 lbs.

An older method often used for valuing skimmilk is to estimate that 100 lbs. of skimmilk are approximately equal in value to one-half bushel of corn. This is a somewhat less accurate basis, for skimmilk replaces both corn and protein supplement, and the prices of corn and supplements do not always rise and fall in the same proportion.

For very young pigs up to 50 or 60 lbs. in weight, skimmilk or buttermilk will have an even higher value than shown in these experiments. Also, the value will be higher when only a very limited amount of skimmilk or buttermilk is fed to pigs in combination with grain and a small amount of other protein supplements.

When considerably more skimmilk or buttermilk is fed than is needed, the additional amount is worth only about one-half as much per 100 lbs. as the quantity that is really needed to balance the ration. Also, the value of these dairy by-products is somewhat less per 100 lbs. for pigs on good pasture than for those in dry lot.[14] This is because good pasture helps furnish some of the nutritive factors that make milk such an excellent feed.

If a ration already contains a sufficient amount of tankage, fish meal, or other efficient protein supplement to balance it properly, it is uneconomical to add skimmilk or buttermilk to it.[15] The other protein supplements should be omitted, or else reduced in amount if there is not enough milk to balance the ration completely.

887. Skimmilk and buttermilk for poultry.—Dairy by-products have high values for poultry. Not only does milk furnish excellent protein, but also its high content of riboflavin is of particular value for poultry. Also, milk supplies niacin, vitamin B_{12}, and certain of the unidentified vitamins. (222) In addition, milk is rich in calcium and phosphorus. The beneficial effect of dairy by-products in poultry rations is partly due to

the effect produced by milk sugar in helping to prevent the development of undesirable bacteria in the digestive tract.

When liquid skimmilk or buttermilk is available, poultry may be allowed to drink all they wish, as a substitute for part or all of the protein supplements usually included in the ration. The amount taken by 100 hens will usually be 12 to 14 quarts a day.

Reasonably good egg production can be secured when hens are fed only grain with all the milk they will drink.[16] Such a ration is much better for hens on good range than for those which are confined.

In summer flies, which are the intermediate host of tapeworms, are apt to be present in large numbers around the vessels in which milk is fed. In Kansas tests the feeding of liquid milk greatly increased the infestation of hens with tapeworms for this reason, but it decreased the number of other worms present in the birds.[17] There was no effect on egg production, but the greater infestation with tape worms might have been more harmful at an early age.

888. Whey.—In making cheese, practically all the casein and most of the fat go into the cheese, leaving in the whey the milk sugar, the albumin, and a large part of the ash. Whey is more watery in composition than skimmilk, containing less than 7 per cent dry matter. Whey from Cheddar and most other types of cheese has about 5.0 per cent milk sugar and 0.3 per cent fat, with only 0.9 per cent protein. Whey from Swiss cheese contains 0.8 to 1.0 per cent fat. To save the fat for butter manufacture, whey (especially from Swiss cheese) is often skimmed at the factories. Skimmed whey is worth slightly less than unskimmed whey.

Whey has only about one-third as much calcium and phosphorus as skimmilk, as whey has but 0.05 per cent calcium and 0.04 per cent phosphorus. It is nearly as rich in riboflavin as is skimmilk.

In feeding whey it is very necessary to bear in mind the fact that most of the protein has been removed, and that whey is not a protein-rich feed, like skimmilk and buttermilk. The milk albumin it does contain is, however, of high efficiency in making good the deficiencies in the proteins of the cereal grains.

Whey is fed chiefly to swine, for which purpose it is worth about one-half as much per 100 lbs. as is skimmilk. It can be used satisfactorily for raising dairy calves when it is fed with a concentrate mixture that is rich in protein. Whey can also be fed to poultry as a source of riboflavin.

Whey should always be pasteurized at the factory to prevent the spread of disease and should be fed under sanitary conditions. Whey soured in clean containers is as valuable as sweet whey, but that from a filthy whey tank may be a very unsatisfactory feed.

889. Whey for dairy calves.—Whey can be successfully used for calf feeding, if it is fed with a suitable protein-rich grain mixture and if it is of sanitary quality. An excellent mixture for feeding with whey is 30 lbs. ground corn, 30 lbs. standard wheat middlings, and 40 lbs. linseed meal.

Two Wisconsin trials show the good results that can be secured with whey under proper conditions.[18] Calves were changed gradually from whole milk to skimmed whey at 3 weeks of age during a period of 10 days. In addition, they were fed clover hay and the protein-rich mixture mentioned previously. The allowance of whey was gradually increased to 14 lbs. per head daily at 6 weeks of age. These calves made normal gains and were vigorous and thrifty, though they did not gain quite so rapidly as calves fed a liberal amount of skimmilk.

890. Whey for swine.—Because of the superior quality of protein in whey, well-grown pigs weighing over 100 lbs. will make excellent gains on a ration of only whey fed with barley or wheat, without any high-protein supplement. For example, in Wisconsin tests such pigs gained even more rapidly on a ration of 7.8 lbs. barley plus what whey they would drink (an average of 18.4 lbs. a day) than others did on barley

and tankage.[19] Likewise, in 2 California experiments pigs fed barley and whey gained nearly as rapidly as those fed barley and skimmilk.[20]

For younger pigs some protein-rich feed, such as linseed meal or wheat middlings, should be added to the grain and whey to balance the ration. It is not necessary to use a protein supplement which furnishes high-quality protein, because of the excellent protein the whey contains, even though the amount of it is small. With corn and whey, a protein supplement should be fed even to pigs over 150 lbs. in weight, for corn has considerably less protein than does barley or wheat. For pigs not on pasture, legume hay should be provided in addition to grain and whey, in order to supply vitamins A and D.

In the Wisconsin trials skimmed whey was worth about one-half as much per 100 lbs. as skimmilk, and the value of whey was even higher in the California trials. Unskimmed whey from American or Cheddar cheese factories will be worth a trifle more than skimmed whey, and unskimmed whey from Swiss cheese factories will have a higher value.

In continental Europe pigs are often fattened on cooked potatoes and whey with a small allowance of grain, and with a protein supplement, at least until they reach a weight of about 130 lbs.[21]

891. Whey for poultry.—Whey in liquid form is not often fed to poultry, but when available, it can be given as a drink or used to moisten the mash. It must be remembered that whey is low in protein and therefore is not a substitute for protein-rich feeds. However, it will fully take care of the riboflavin requirements.

892. Dried skimmilk; dried buttermilk.—Considerable quantities of skimmilk and buttermilk are dried at the factories to produce dried skimmilk and dried buttermilk. Because of their high value in human foods, these products are commonly too high in price to be used largely for stock feeding. A small percentage is often included in poultry mashes, especially for chicks and broilers, and they are also used in calf starters and milk replacers for dairy calves and in pig starters or in mixtures for creep-feeding pigs.

Dried skimmilk sold for human food is now called "nonfat dry milk solids" or "defatted milk solids" under Federal regulations. When sold for livestock feeding it is commonly called dried skimmilk, dried skimmed milk (feeding), dry skimmilk, or powdered skimmilk.

One pound of dried skimmilk or of dried buttermilk has approximately the same composition and feeding value as 10 lbs. of liquid skimmilk or buttermilk, respectively. Dried skimmilk contains an average of 33.1 per cent protein, 51.1 per cent milk sugar, 8.0 per cent minerals, and 1.1 per cent fat. Dried buttermilk is a little lower in protein and appreciably lower in nitrogen-free extract (chiefly milk sugar), but has an average of 6.1 per cent fat. Because of the alkalies used in partially neutralizing very sour cream, dried buttermilk is higher than dried skimmilk in minerals. According to the definition of the American Association of Feed Control Officials, dried buttermilk (feeding) must not contain more than 8 per cent of water or more than 13 per cent of mineral matter, and must have not less than 5 per cent of butterfat.[22]

Dried skimmilk and dried buttermilk are very rich in riboflavin, and their high value in poultry feeding is due largely to this fact.

893. Dried skimmilk; dried buttermilk for dairy cattle.—As is pointed out in Chapter XXVII, dried skimmilk or dried buttermilk is an excellent protein supplement for use in a "calf starter," or calf meal, for raising dairy calves in market-milk and condensary districts, where skimmilk is not available. In such localities calves are also often raised on reconstituted, or remade, skimmilk or buttermilk. This is prepared by mixing dried skimmilk or dried buttermilk with warm water at the rate of 1 lb. to 9 lbs. of water. First mix the dried product to a smooth paste with an equal weight of cold water and then add 8 parts more of warm water. This solution will have practically the same composition as fluid

skimmilk or buttermilk, and can be used like skimmilk in raising calves.

When the reconstituted milk is fed in the same manner and in the same amounts as skimmilk or buttermilk, nearly as good results can be secured with it.[23] The difficulty is that these dried products are often expensive. Changes can be made freely from skimmilk to reconstituted skimmilk or from buttermilk to reconstituted buttermilk, if the supply of the fluid by-products varies from day to day.

Unless the feeding of some whole milk is continued for at least 3 to 4 weeks, the calves are apt not to thrive or to make good gains on such reconstituted milk.[24] This is often the case, even when a supplement is added to supply the vitamin A value that skimmilk lacks.

Recently, surplus dried skimmilk, purchased by the United States Government under the price support plan, was released and sold to feed manufacturers at a price comparable to that of other common protein supplements. A New York test at that time showed that 5 or 10 per cent of dried skimmilk was a very satisfactory substitute for linseed meal in a concentrate mixture for dairy cows.[25] In earlier Wisconsin trials dried skimmilk or dried whey did not have any effect on milk production when included in the concentrate mixture, but dried whole milk caused a small increase in fat test.[26]

894. Dried skimmilk; dried buttermilk for swine.—These dried dairy by-products are generally too expensive to be economical protein supplements for swine, except perhaps for very young pigs. They have a considerably higher value, in comparison with tankage or fish meal, for dairy calves being raised on a minimum amount of milk and for poultry, than they do for swine.

If no fluid skimmilk or buttermilk is available for young pigs at weaning time and for a few weeks afterward, a little more rapid growth results when 2 to 5 per cent of dried skimmilk or dried buttermilk is included in the ration. However, the cost of the gains is generally less when such a protein supplement as the trio mixture is fed, without the dried dairy by-products.[27]

When maximum growth of purebred pigs is desired, regardless of the expense, and no fluid skimmilk or buttermilk is available, excellent results are secured when 5 to 10 per cent of dried skimmilk or dried buttermilk is included in the ration, at least until the pigs reach a weight of 50 to 75 lbs. These dairy by-products should not be self-fed separately, free-choice, for they are so palatable that the pigs will eat much more than they need.

If dried skimmilk or dried buttermilk is used as the only protein supplement, a much larger proportion is needed to balance a ration than with tankage, meat scrap, or fish meal. This is because of the much lower protein content of these dried dairy by-products. For this reason, dried skimmilk and dried buttermilk have been worth only about 90 per cent as much a ton as tankage or fish meal in experiments where they have been used as the only protein supplement, and the cost is generally much higher than this.[28]

895. Dried skimmilk; dried buttermilk for poultry.—These dairy by-products are now used much less commonly in poultry rations than some years ago, because of their wide use in human foods. Instead, dried whey and other whey products are more general in formula poultry mashes.

In early experiments the results with both chicks and laying hens were usually better when dried skimmilk or dried buttermilk was used in the ration than without any dairy by-product. However, with the modern knowledge of animal nutrition, it is now possible to make just as efficient rations without them. In such rations the vitamins and high-quality protein furnished by milk products are supplied by other supplements.[29]

Sometimes 1.0 to 2.5 per cent or more of dried skimmilk or dried buttermilk is included in poultry mashes, especially for chicks and broilers.

896. Dried whole whey; other dried whey products.—Dried whole

whey, also called dried whey, is made by drying whey from cheese manufacture or from the manufacture of casein from skimmilk. It has an average of 12.8 per cent protein and 70.1 per cent milk sugar. One pound of dried whey is equal to 13 or 14 lbs. of liquid whey in nutrients.

Dried whey is especially rich in riboflavin and pantothenic acid, and has a good content of niacin and vitamin B_{12}. It also supplies two of the unidentified B-complex vitamins. (222) Due to its high lactose content, dried whey is very laxative, if too much is included in a ration.

Because of its high riboflavin content, dried whey is used chiefly in poultry feeds.[29] It is also used in some "calf starters," or calf meals. Dried whey is also included in some supplemental mixtures for pigs, especially for young pigs.[30] Its value for pigs seems to be somewhat lower than for poultry. By a special process of fermentation before drying, fortified dried whey is made which is particularly high in riboflavin.

Dried whey-product is the dried product resulting from the partial removal of milk sugar from clean, sound whey.[22] It has more protein but less lactose than dried whey, and is used similarly in poultry rations.

Dried whey solubles is the product resulting from the removal of albumin and the partial removal of milk sugar from whey.

897. Condensed or evaporated dairy by-products.—*Condensed or evaporated buttermilk*, also called "concentrated buttermilk" and "semi-solid buttermilk," is made by evaporating buttermilk until it is reduced to about one-third the original weight. Though condensed buttermilk is semi-solid, it generally contains about 70 per cent water, and fully 3 lbs. are required to equal 1 lb. of dried buttermilk or dried skimmilk in amount of milk solids. It is usually more expensive than an equivalent amount of dried skimmilk or buttermilk, because it must be shipped in water-tight containers and because of the greater cost of transporting the watery product. Similar *condensed skimmilk* is sometimes produced, and also *condensed cultured*, or *soured, skimmilk*.

According to the definitions of the Association of American Feed Control Officials, these condensed products must have not less than 27 per cent total solids.[22] Condensed buttermilk must have not less than 0.055 per cent of butterfat and not more than 0.14 per cent of ash for each per cent of solids.

Condensed buttermilk or condensed skimmilk is used chiefly for poultry feeding, but it has been replaced largely by dried buttermilk or dried skimmilk, because of their lower cost per pound of milk solids. In a study of the cost of producing broilers in Arkansas it was found that the poultrymen who fed condensed milk supplements in addition to the other feed made less profit than those who fed none of these condensed products.[31]

Condensed buttermilk may be used in the same manner as dried buttermilk in making reconstituted buttermilk for feeding dairy calves.[32] However, it takes about 3 lbs. of condensed buttermilk to 7 lbs. of water to equal fluid buttermilk in nutrients. If a more dilute solution is fed, as is often done, the feeding of a given amount of the solution will obviously not produce as good gains as the same weight of skimmilk or buttermilk. The acidity in semi-solid buttermilk sometimes causes calves to scour severely, and it is then necessary to neutralize it with lime water before feeding.

In numerous experiments with pigs, slightly more rapid gains have usually been made when condensed buttermilk has been added to good rations containing no milk product, or when it has been used as a substitute for tankage or other common supplements.[33] However, the gains have been much more expensive. In Wisconsin tests there was no benefit from adding 0.15 lb. of condensed buttermilk (diluted with 30 parts of water) to a ration of corn and the trio supplemental mixture for pigs.[34]

Condensed whole whey is the product resulting from the removal of a considerable part of the water from clean, sound cheese or casein whey.[22] It should contain not less than 62 per cent of total whey solids.

Condensed whey-product is the similar product resulting from the removal of a considerable part of the water and the partial removal of milk sugar from whey. It should have not less than 50 per cent of total whey solids.

Condensed whey solubles is a product resulting from the removal of albumin and the partial removal of milk sugar from whey. These whey by-products are used chiefly for

poultry, but can also be used for dairy calves or pigs.

898. Cheese rind, or cheese meal.—This by-product from the manufacture of processed cheese consists of the cheese trimmings, from which most of the fat has been removed. It contains about 60 per cent protein and 9 per cent fat, thus resembling the best grades of tankage in composition. In Wisconsin tests cheese meal was an excellent protein supplement for pigs or poultry.[35] As it is more expensive than tankage or meat scrap, it had best be used to replace not more than half the amount of these supplements usually fed.

II. Meat and Fish By-products

899. Meat by-products.—The meat by-products used for livestock feeding come from three sources: First, from the meat scrap, fat trimmings, and offal at the meat-packing plants and slaughter houses; second, from meat scrap of butcher shops, hotels, etc.; and third, from dead animals processed for soap grease at rendering plants. The various meat by-products include tankage, meat scrap, meat-and-bone scrap, blood meal, and the different types of bone meal.

900. Meat scrap; meat-and-bone scrap; digester tankage.—Two methods are used in processing meat by-products. In the newer method—the dry-rendering method—the waste meat by-products are cooked in an open steam-jacketed vessel until the moisture has evaporated. Then the fat is drained off, the solid residue is pressed to remove as much of the fat as possible, and the dry residue is granulated or ground into a meal. This product is called *meat scrap, meat meal,* or sometimes dry-rendered tankage. Sometimes meat scrap or meat meal is solvent extracted to remove more of the fat.

In the wet-rendering method, which is older, the raw material is thoroughly cooked by steam under pressure in closed tanks. The fat is then skimmed off, the soupy liquid drained off, and the solid residue pressed to remove as much of the fat and water as possible.

The liquid is evaporated down until it becomes gluey, then being called "stick." This is added to the solid residue, and the mixture dried and ground. This product is designated as *digester tankage,* or *feeding tankage.* It is generally called merely "tankage." The wet-rendering process is being largely replaced by the dry-rendering method, as the latter is more efficient.

The best grade of tankage is usually guaranteed to contain 60 per cent protein. Often partly-dried blood is added before drying, to bring the protein content up to the desired amount. Some digester tankages contain only 55 per cent protein. The tankages produced at small rendering plants may have only 40 to 50 per cent protein.

According to the definitions of the Association of American Feed Control Officials meat scrap or tankage should not contain hair, hoof, horn, hide trimmings, manure, or stomach contents, except in such traces as might occur unavoidably in good factory practice.[22]

Meat scrap usually contains only 50 to 55 per cent protein, but is about equal in feeding value to digester tankage containing 60 per cent protein. This is probably because the protein in meat scrap has a higher nutritive value since it is subjected to less heat. Meat scrap does not have so strong an odor as digester tankage and is lighter in color. It does not contain blood meal or "stick."

When tankage or meat scrap contains so much bone that the phosphorus content exceeds 4.4 per cent, the word "bone" must be included in the name, such as meat-and-bone scrap, or digester tankage with bone.

Certain meat by-products that do not contain enough fat to be used as sources of grease or tallow are dried directly and marketed as high-protein meat meals, or are blended with tankage or meat scrap.

901. Value and use of meat scrap and tankage.—Meat scrap and tankage are used chiefly as protein supplements for swine and poultry. Meat scrap is generally preferred to tankage for poultry.

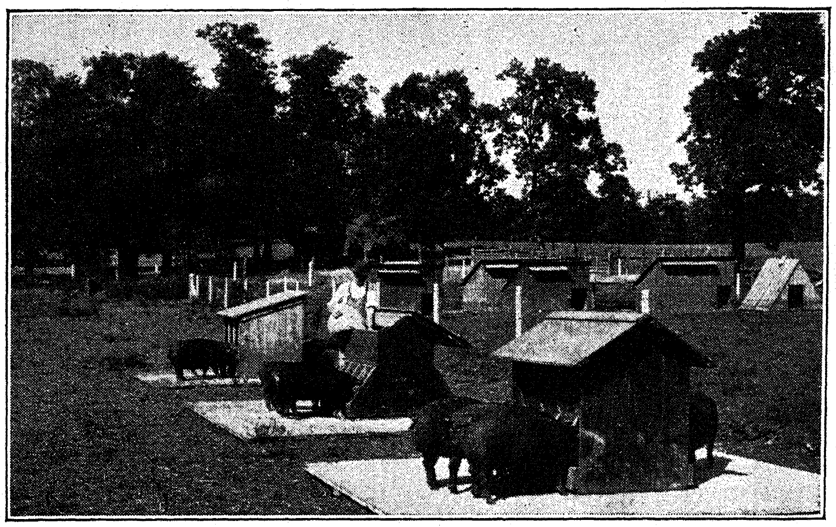
High-grade meat scrap and tankage are not only very rich in protein, but also the protein effectively corrects the deficiencies in the protein of the cereal

grains. These animal by-products are high in lysine, but supply less methionine and tryptophan than does fish meal, and have less tryptophan than soybean oil meal, linseed meal, cottonseed meal, or peanut oil meal. Since corn is very low in tryptophan and the other grains rather low, meat scrap or tankage gives the best results when combined with a protein supplement that is higher in this amino acid.

Meat scrap and tankage are excellent sources of vitamin B_{12} and are rich in niacin and choline. They also supply certain unidentified vitamins that are important in poultry and swine rations. (222) They do not supply vitamin A or vitamin D and are rather low in riboflavin.

Meat scrap and tankage are especially rich in phosphorus and calcium, chiefly because of the bone content.

Meat scrap and tankage do not have the special value for dairy cows, beef cattle, sheep, or horses, that they have for swine or poultry. This is because the kind or quality of protein in the ration is of far less importance for ruminants and for horses. (112) However, meat scrap or tankage may be used for these classes of stock, when they are a cheaper source of protein than such plant-protein supplements as soybean oil meal, cottonseed meal, or linseed meal. While these animals may at first not like the feeds, generally they will soon eat a mixture of concentrates containing the small proportion of a meat by-product that is needed to balance the ration. Occasionally, a certain lot of tankage or meat scrap may prove unpalatable to cattle.



TANKAGE OR MEAT SCRAP CAN BE SELF-FED, FREE-CHOICE

When pigs are self-fed, free choice, on corn and tankage or meat scrap in separate compartments of a self feeder, they eat the proper proportion of supplement to balance the ration. (From Wisconsin Station.)

With dairy cows, beef cattle, and sheep the results are apt to be better when tankage or meat scrap is combined with better-liked supplements, than when used as the only protein supplements.

902. Variations in value of tankage and meat scrap.—The nutritive value of tankage and meat scrap unfortunately varies considerably, depending chiefly on the kind of raw material from which they are produced. If they consist too largely of waste that is high in gristle, connective tissue, or bone, the value will be much lower than in the case of a

product containing more meat. This is because the protein in gristle and connective tissue, and also in bone, is of low value. (121) Moreover, some tankages contain too large a proportion of stick or of blood meal, both of which supply protein of rather low quality. Such poor-quality products may have as high percentages of protein and fat as high-grade tankage or meat scrap.

As it is impossible for the usual purchaser to detect the poor quality by ordinary inspection, it is wise to buy those products which are made by establishments of known reputation for high quality. Occasionally, products are found on the market which are adulterated with such materials as hoof meal, ground hair, leather meal, rumen or intestinal contents, etc.

The meat scrap and tankage produced in recent years have tended to be of lower value than the products made earlier. This is because these by-products usually now have a smaller proportion of hearts, livers, kidneys, beef trimmings, and glandular materials, all of which supply good-quality protein. More of some of these materials are now used for human consumption and considerable amounts are used in dog and cat foods, or for fur animals. This change naturally decreases the value of these animal by-product feeds. It makes it even more desirable than formerly to feed pigs not on pasture one of the efficient supplemental mixtures discussed in Chapter XXXIV, instead of using tankage or meat scrap as the only supplement to grain.

Robison of the Ohio Station has reported that in 9 experiments conducted up to 1920 pigs fed corn and tankage in dry lot made an average gain of 1.30 lbs. and required 389 lbs. feed per 100 lbs. gain.[36] In 16 similar later experiments the daily gain was only 1.02 lbs. and 410 lbs. of feed were eaten per 100 lbs. gain.

On prolonged storage the fat in such feeds as meat scrap, tankage, and fish meal tends to become rancid, through the splitting of free fatty acids from the fat. A high content of free fatty acids in these feeds may be detrimental, probably not because the fatty acids are injurious, but because of destruction of vitamins and other changes which have occurred.

903. Rendering-plant tankage, or reduction tankage.—The rendering plants, which render scrap meat and bones from butcher shops, dead animals, etc., for soap grease, produce tankage of various qualities. This rendering-plant or reduction tankage is used chiefly for fertilizer, but some is fed to stock. The high temperature in the rendering process thoroughly sterilizes rendering-plant tankage, but care is necessary in the plant to prevent contamination of the product by contact with rats, or with particles of incoming material, carried on the shoes of the workers. If some of the raw material has begun to decompose before it is processed, the tankage may be unsuitable for feeding, and may be injurious.

It is not surprising that the results have differed widely in the experiments in which rendering-plant tankage has been compared with high-grade tankage.[37] In some tests low-protein tankage having only 35 to 45 per cent protein has been worth fully as much as high-grade tankage per pound of protein actually contained. However, in other trials much less satisfactory results have been secured with rendering-plant tankage. Safety lies only in purchasing rendering-plant tankage made by a concern that has a reputation for producing a product of good quality.

904. Tankage; meat scrap; meat-and-bone scrap for swine.—For swine feeding, tankage and meat scrap are the most commonly used high-protein supplements of animal origin. For this reason, they have generally been the standards with which other protein supplements have been compared in experiment station tests. These feeds are widely used as supplements for growing and fattening pigs and also for breeding stock.

Tankage and meat scrap are very satisfactory as the only protein supplements to grain for pigs or brood sows on pasture. For swine not on pasture, field-cured legume hay of good quality should

also be included in the ration wherever possible. This provides vitamin A, vitamin D, and other vitamins that may be deficient when swine are fed in dry lot for long periods. The addition of legume hay is especially important for young pigs and brood sows during winter in the northern states. It is shown in Chapter XXXIV that certain protein supplemental mixtures are even more efficient for pigs in dry lot than the combination of tankage and alfalfa or other legume hay.

Though excellent results are generally secured when tankage is used as the only supplement to grain for pigs on good pasture, it is shown elsewhere that combinations of tankage and other supplements may produce more rapid and economical gains, especially when self-fed by the free-choice method. Thus, a mixture of one-half tankage and one-half linseed meal, soybean oil meal, or cottonseed meal is slightly superior for feeding in this manner as a supplement to corn for pigs on pasture.

Meat scrap is somewhat superior to digester tankage having approximately the same percentage of protein.[38] In 6 Ohio trials 55 per cent protein meat scrap was slightly more valuable than 60 per cent protein digester tankage.[39] On the other hand, meat-and-bone scrap of the 50 per cent protein grade is generally worth appreciably less than 60 per cent protein tankage. In 14 trials pigs on pasture, fed such meat-and-bone scrap as the supplement to corn, gained as rapidly as those fed digester tankage, but they required a little more feed per 100 lbs. gain.[40] On the average, 100 lbs. of the meat-and-bone scrap were equal in value to 85.4 lbs. of the higher-protein digester tankage plus 2.5 lbs. of corn.

When pigs are self-fed corn and tankage or meat scrap, free-choice, in separate compartments of a self-feeder, they will usually eat about the correct proportions of these feeds to make a well-balanced ration, no matter whether they are in dry lot or on pasture. Because of the convenience and saving of labor, this method of feeding is popular. Occasionally, pigs either overeat on tankage or else fail to take enough to balance their ration properly. In such cases, it may be necessary to discontinue free-choice feeding and either self-feed them a mixture of ground corn and tankage in the proper proportions or else self-feed the shelled corn and hand-feed the tankage.

When pigs are self-fed such combinations as barley or wheat with tankage, free-choice, they frequently overeat on tankage so much as to increase the cost of the gains decidedly. Free-choice feeding of such combinations is not, therefore, to be recommended generally. Instead, a mixture of the proper proportions of ground grain and tankage should be fed, or the grain may be self-fed and the necessary amount of tankage hand-fed twice daily.

When pigs are hand-fed their rations, it makes no difference whether the tankage is mixed with the other feed in suitable proportions or whether the proper amount to balance the ration is fed separately. There is no advantage in feeding the tankage in the form of a slop or in soaking it.

The proportions of tankage or meat scrap needed to balance various rations for swine are shown in Appendix Table VII.

905. Meat scrap; meat-and-bone scrap; tankage for poultry.—Meat scrap is the most widely used protein supplement of animal origin in poultry feeding and is a common ingredient of poultry mashes. It is well liked by poultry and supplies protein that corrects the deficiencies in the proteins of the cereal grains and their by-products. The proportions of meat scrap generally used in poultry feeding are indicated by the example rations in Appendix Table VII.

The quality of protein in meat scrap containing 55 per cent or more of protein is apt to be better than in meat-and-bone scrap, which is lower in protein content.[41] Tankage can replace meat scrap in poultry rations, but most poultrymen decidedly prefer meat scrap.

906. Tankage or meat scrap for dairy cattle.—Although these animal by-products are not commonly used for dairy cows, they are satisfactory when

they furnish protein at lower cost than do such feeds as soybean oil meal or cottonseed meal.[42] Dairy cows will usually eat concentrate mixtures containing 8 to 17 per cent tankage satisfactorily. Occasionally some cows do not like such a mixture at first, though later they will eat it readily.

The milk production is not increased by substituting tankage or meat scrap for the protein supplements ordinarily fed dairy cattle, and it may even be reduced a trifle. These animal by-products have not affected the flavor or odor of the milk, even when fed 1 to 2 hours before milking.

Meat scrap or tankage can be used as a protein supplement in "calf starters," or calf meals, but had best replace only part of the dried skimmilk, other dairy by-products, or soybean oil meal.

907. Tankage or meat scrap for beef cattle.—Tankage or meat scrap is of much less value for beef cattle than for swine or poultry. In 10 experiments fattening cattle fed either tankage or meat scrap as the only protein supplement gained 0.1 lb. less per head daily than similar cattle fed linseed meal, cottonseed meal, or soybean oil meal as the supplement.[43] Where the selling price of the cattle was reported in these trials, it was slightly less for the cattle fed tankage or meat scrap. While the value of these animal by-products varied widely in these experiments, on the average they were worth less per ton than the plant-protein supplements.

Tankage was also inferior to cottonseed meal or corn gluten meal in Kansas tests in which 1 lb. per head daily of these various supplements was fed to calves and yearlings being wintered on Atlas sorghum silage.[44]

It is best to accustom cattle to tankage or meat scrap gradually by mixing a small proportion at the start with better-liked feeds, such as linseed meal, cottonseed meal, or ground grain. Tankage or meat scrap has given better results with beef cattle when used in mixed protein supplements, combined with such feeds as linseed meal, cottonseed meal, and soybean oil meal.

908. Tankage or meat scrap for sheep.—Tankage or meat scrap can be substituted for such protein supplements as soybean oil meal in feeding sheep. Sheep may not like these animal by-products at first, but after a few days will usually eat the small amount needed to balance the ration, especially if mixed with well-liked feeds. Sometimes fattening lambs tire of meat scrap or tankage toward the end of the feeding period.

The results of experiments in which either digester tankage or meat scrap has been used as the only protein supplement for fattening lambs have differed somewhat.[45] In some of the trials the results have been fully as good or even slightly better than with cottonseed meal or linseed meal, but in other tests the gains have been more rapid on the latter supplements.

909. Tankage or meat scrap for horses.—One to 2 lbs. a day of either of these feeds, or 1 lb. of blood meal, is sometimes useful for run-down, thin horses. As these feeds are not liked by horses, they must be mixed with palatable feeds.

910. Blood meal; blood flour.—*Blood meal*, or dried blood, is made from the blood collected at packing plants. It is first heated until it is thoroughly coagulated; the excess water is then drained off; more moisture is removed in a press; and finally, the solid residue is dried and ground.

Blood meal is the highest in protein of all the packing-plant by-products, containing over 80 per cent. However, the protein is less digestible and of much poorer quality than that in high-grade tankage or meat scrap. Blood meal is low in calcium and phosphorus, thus differing again from tankage or meat scrap. It is used chiefly in "calf starters," or calf meals, for raising dairy calves on a minimum of milk. Blood meal is not usually liked by calves at first, and if it is used as the chief protein supplement in a calf meal, it may be difficult to get them started on it.

Sometimes blood meal is used in poultry feeds, but it is unpalatable to

poultry and is inferior to meat scrap in value.[46] Tankage is usually better and cheaper for young pigs.[47] In a Massachusetts test 10 per cent of blood meal was a fairly good substitute for other protein feeds in a concentrate mixture for dairy cows.[48]

Blood flour, or soluble blood meal, is produced by special processes, and is more soluble than ordinary blood meal. It is considered preferable in calf meals, but in an Ohio trial ordinary blood meal equaled soluble blood flour.[49]

911. Hoof and horn meal.—Experiments have shown that when animal hoofs and horns are ground to an extremely fine powder in a ball mill, the product can be digested by animals and can be used to replace part of the usual protein supplements for poultry. The product seems to be decidedly variable, however, and sometimes does not give satisfactory results.[50]

912. Feather meal.—Feather meal, or hydrolized feathers, is a new product made by treating under high steam pressure the feathers from slaughtered poultry. It has over 80 per cent protein, and according to the definition proposed by the Association of American Feed Control Officials, should have 70 per cent digestible protein.[22] The results of the few trials reported with feather meal have differed, apparently due to variations in quality.[51]

Feather meal properly made can apparently replace part of the ordinary protein supplements in rations. Satisfactory results have been reported with 2 to 5 per cent in a broiler mash. Feather meal seems to supply vitamin B_{12} and one of the unidentified factors needed by chicks. (**222**)

913. Liver meal.—Various types of liver meal, made chiefly from animal or fish livers, are used primarily as vitamin supplements, but also supply high-quality protein. *Animal liver meal* should be made entirely from liver. *Animal liver and glandular meal* is made from liver and other glandular tissue and at least 50 per cent of the dry matter should be from liver.[22] Similar products are made from fish by-products.

Liver meals are used chiefly as vitamin supplements in poultry mashes or in special feeds for pet stock and fur animals, because of the content of riboflavin and other B-complex vitamins. Adding 2 per cent of liver meal to a ration for very young pigs in dry lot may increase the thriftiness and gains, but may be uneconomical, because of the high price.[52]

914. Low-grade animal fat.—Due in large part to the wide use of detergents in place of soaps in this country, there has recently been a surplus of low-grade animal fats, produced in the meat and rendering industries. (**134**) As a result, the prices of these tallows and greases have declined to levels that make their use in formula feeds, or mixed commercial feeds, practical. The use of these fats is discussed in Chapter V and in the chapters dealing with the different classes of stock. To prevent the development of rancidity in the fat and resulting destruction of vitamins in the feed, an effective antioxidant should be added to the fat.

915. Paunch fluid, dried.—In Wisconsin tests a product rich in B-complex vitamins was prepared experimentally by pressing out and drying the fluid that could be pressed from the paunch contents of cattle or sheep at a slaughter house.[53] It was about as rich as dried skimmilk in riboflavin.

916. Poultry by-product meal.—This by-product of poultry processing plants consists of the ground, dry-rendered, clean, wholesome parts of the carcasses of slaughtered poultry, such as head, feet, undeveloped eggs, gizzard and intestines, exclusive of feathers and gizzard and intestinal contents, except in such trace amounts as might occur unavoidably in good factory practice.[22] Limited data indicate that it may be a satisfactory substitute for meat scrap.[54]

917. Fish meal.—Years ago most of the fishery wastes were either used to make fish meal for fertilizer or were not utilized at all, but dumped in the sea. Because of the numerous experiments which proved the high value of fish meal for swine and poultry, the production of fish meal has increased until it has become an important protein supplement.

Several types of fish meal are made, differing both in the raw material used and in the method of drying. Menhaden fish meal is the most common kind in the eastern states. This is made in processing menhaden herring (a very fat fish not suited for food) for fish oil and fish meal. White fish meal is made chiefly

from the cuttings or waste of the cod and haddock industry, not including the entrails, which, except the livers, are dumped at sea. Other fish meals are made of waste from sardines, herring, salmon, tuna, etc.

At first, fish meal was nearly all dried in so-called "flame driers," in which the material was exposed to high temperatures. This method has been largely replaced by drying in steam-jacketed drums, often under partial vacuum, to lower the temperature. Vacuum-dried fish meal is superior to flame-dried fish meal made from the same material, as it has a higher content of vitamins and the protein is more digestible.

In the case of fish cuttings that are high in fat or oil, most of the oil is expressed from the product. A high fat content in fish meal is undesirable, as such fish meal may produce a fishy taste in eggs, meat, or milk. Also, fish meal high in fat is more apt to become rancid on storage.

918. Nutritive value of fish meals. —Fish meals differ somewhat in nutritive value, depending on the type of raw material used, the method of drying, and the care taken in the process. But few direct comparisons have been made of the various kinds of fish meal, and therefore only general statements can be given concerning their relative feeding value.

Fish meal of good quality has an especially high value for swine and poultry, because of the excellent quality of protein it supplies. However, the protein quality in different samples of fish meal varies decidedly. In more than a hundred samples of various commercially produced fish meals recently tried in California experiments, only about half were rated as good in protein quality.[55] In these tests sardine fish meals, which comprised the greatest number of samples, were generally of high quality.

Apparently, some fish meal producers should use much more care in making their product. If decomposition of the fish waste occurs before it is processed, the fish meal may be injurious and entirely unsuitable for feeding. Obviously, much more care must be taken to prevent decomposition in the production of fish meal for stock feeding than in making fish meal for fertilizer. Certain fish waste is too high in salt to be used to make fish meal for feeding, unless the salt is removed from the product.

Fish meal is very rich in protein, containing 60.9 per cent, on the average. Also, the protein of good-quality fish meal is of high nutritive value, tending to be more efficient than the protein of tankage or meat scrap as a supplement to the grains. If fish meal contains too large a proportion of fish heads, the value of the protein is decreased, because much of the protein in the heads is less digestible and of lower nutritive value than the protein in the flesh.

Herring fish meal is the highest in protein content, averaging 72.5 per cent. Sardine, menhaden, and white fish meal all average above 60 per cent in protein, while fish meal from redfish, salmon, and tuna usually has somewhat less protein.

Fish meal usually has 6 to 10 per cent of fat, but some fish meal is now made which has only 3 to 4 per cent fat.

Because of the bones it contains, fish meal is high in calcium and phosphorus. It has an average of 5.36 per cent calcium and 3.42 per cent phosphorus, with a total mineral-matter content of 18.3 per cent. It should also be noted that fish meal usually contains an appreciable amount of iodine. However, in regions where there is an iodine deficiency for livestock, iodine can readily be supplied at less expense in the form of iodized salt. (**170**)

Fish meal is one of the richest sources of vitamin B_{12} among common feeds and also of one of the unidentified vitamins required by poultry. (**222**) It is also fair in riboflavin content and has considerable niacin. Fish meal processed under partial vacuum may contain considerable vitamin A and vitamin D, but other fish meals may have little of these vitamins.

Some have hesitated to use fish meal for stock feeding, fearing that it might cause a fishy flavor in eggs, meat, or milk. In the numerous feeding experiments

with fish meal no injurious effect has been produced when good fish meal, not unduly high in fat, has been fed in such amounts as were needed to balance the ration. If a larger allowance of fish meal is fed there may be danger of producing a fishy flavor.

919. Fish meal for swine.—Numerous experiments have shown that fish meal of good quality is even superior to tankage or meat scrap as a protein supplement for swine. Fish meal produces very satisfactory results when used as the only protein supplement to grain for pigs or brood sows on pasture. For swine not on pasture, field-cured legume hay of good quality should be included in the ration, if possible, to make sure that there is a plentiful supply of vitamin A, vitamin D, and the B-complex vitamins. It is shown in Chapter XXXIV that the results are especially good when fish meal is used in one of the efficient trio-type supplemental mixtures, which includes alfalfa or other legume hay and also a protein supplement of plant origin, such as linseed meal or soybean oil meal.

When fish meal is used in place of tankage or meat scrap in a trio-type supplemental mixture, there is not much difference in the value of these protein supplements. For example, in 11 New York and Ohio experiments pigs fed fish meal in trio-type supplemental mixtures gained an average of 1.51 lbs. a day and required 383 lbs. of feed per 100 lbs. gain.[56] Similar pigs fed tankage or meat scrap in the trio-type mixtures gained 1.47 lbs. a day and required 385 lbs. of feed per 100 lbs. gain. Fed in this manner, the fish meal was worth only about 5 per cent more per ton than tankage or meat scrap.

When fed as the only protein supplement to grain for pigs not on pasture, fish meal is decidedly superior to tankage or meat scrap. In 18 trials pigs fed fish meal as the only protein supplement to corn in dry lot gained 1.68 lbs. daily, on the average, and required 349 lbs. corn and 35 lbs. fish meal per 100 lbs. gain.[57] Others fed digester tankage gained 1.46 lbs. a day and required 381 lbs. corn and 37 lbs. tankage per 100 lbs. gain. In these trials each 100 lbs. of fish meal was equal in value to 106 lbs. digester tankage plus 91 lbs. corn, without considering the advantage of the more rapid gains.

Fish meal has also been superior to tankage when fed as the only supplement to corn for pigs on pasture, but the difference in value of the two supplements has not been so great as for pigs in dry lot. In 11 experiments with pigs on pasture, the average daily gain has been 1.59 lbs. on fish meal and corn, in comparison with 1.49 lbs. on tankage and corn.[58] In these trials each 100 lbs. of fish meal has been equal in value to 113 lbs. tankage plus 19 lbs. corn.

Especially good results are secured with certain complex protein supplements that include both fish meal and also meat scrap or meat-and-bone scrap.

Only a few comparisons have been made of the relative values of the different kinds of fish meal, but they are all apparently very satisfactory when made from raw material of suitable quality for feeding and when not unduly high in fat.[59]

If pigs are fed considerably more fish meal than is needed to balance the ration, or if the fish meal is unduly high in fat, a fishy flavor may be produced in the pork.[60]

920. Fish meal for poultry.—Good fish meal is an excellent protein supplement for poultry, the quality of the protein being somewhat superior to that in meat scrap.[61] Also, the B-complex vitamin content is important. However, most fish meals are not so palatable to poultry as meat scrap, and therefore not more than 5 to 10 per cent should be included in the ration.

Fish meal does not give a fishy flavor to the flesh of chickens or to eggs when the fish meal is of good quality and when the ration contains no more than 5 to 10 per cent. Fish meal may affect the flavor of turkeys if it is fed during the fattening period. It is therefore best to feed no fish meal for at least 8 weeks before marketing them.[62]

921. Fish meal for cattle, sheep, and horses.—If fish meal is a cheaper source of protein than protein supplements of plant origin, it can be used economically for cattle or sheep. However, for these classes of stock a pound of protein in fish meal usually has no higher value than in such supplements as linseed meal, soybean oil meal, or cottonseed meal. Also, fish meal is often not palatable to cattle or sheep. They will usually become accustomed to a concentrate mixture containing 10 to 15 per cent of fish meal, but occasionally animals will refuse to eat such a combination.

In most of the experiments in which fish meal has been fed to dairy cows, the yields of milk and fat have been satisfactory, but in some instances the fish meal has slightly decreased the percentage of fat in the milk.[63] The same effect is produced by cod-liver oil and certain other fish oils. Often the mixture containing fish meal has been less palatable to cows than the usual type of dairy concentrate mixture. Fish meal is sometimes used to furnish part of the protein in calf meals, or "calf starters," for dairy calves being raised on a minimum amount of milk.

Fish meal of good quality has produced satisfactory results when used as a protein supplement for fattening lambs or fattening cattle.[64] It is occasionally fed to horses.

922. Condensed fish solubles; homogenized condensed fish.—*Condensed fish solubles* are made by evaporating to a semi-solid condition the watery solution which is expressed, along with the oil, when fish or fish wastes are processed. They have about 50 per cent dry matter and 30 per cent protein. The chief value of condensed fish solubles is due to the high content of certain B-complex vitamins. They may contain about as much riboflavin as dried skimmilk; they are rich in pantothenic acid, especially high in niacin, and even higher than fish meal in vitamin B_{12}. They also provide one of the unidentified vitamins important in poultry feeding. A small amount of dried fish solubles is also made.

Experiments have shown that for swine[65] or poultry[66] kept continuously in confinement, with no access to green feed, adding 2 to 3 per cent or more of condensed fish solubles decidedly improves rations that have little or no protein supplement of animal origin.

Homogenized condensed fish, or liquid fish, is a partially dehydrated product made from fish and/or fish cuttings from which part of the oil has been removed. It should contain not less than 50 per cent of dry matter, exclusive of any added salt. It is used in the same way as condensed fish solubles.

923. Crab meal.—Crab meal is made from the waste of the crab industry and contains the shell, viscera, and parts of the flesh. It is much lower in protein and higher in mineral matter (chiefly calcium carbonate) than is fish meal, for it has an average of 40.9 per cent mineral matter and only 31.6 per cent protein. For poultry it is a satisfactory substitute for fish meal, when it is used in combination with other protein supplements and if the calcium content of the ration is adjusted properly.[67] It requires about 4.0 lbs. of crab meal to replace 2.5 lbs. of fish meal.

In a Pennsylvania trial crab meal was a satisfactory protein supplement for pigs, but in a South Carolina test pigs would not eat enough of a mixture of crab meal and cottonseed meal to balance their ration properly.[68]

924. Gelatin.—The protein in gelatin has a low nutritive value, and therefore gelatin is not satisfactory as a substitute for tankage in stock feeding.[69] A by-product composed chiefly of gelatin, called "alba blood," made from discarded printers' rolls, has been sometimes used as an adulterant in tankage.

925. Shrimp meal.—Shrimp meal is the dried waste of the shrimp industry, consisting of the heads and hulls (or shells), and perhaps some whole shrimp. It is steam-dried or dried in the sun, in which case salt is commonly added to prevent spoilage. According to the regulations of the Association of American Feed Control Officials, it must not contain more than 7 per cent of salt, and if it has more than 3 per cent, the amount must be stated.[22]

Shrimp meal has an average of 46.7 per cent protein and 27.8 per cent mineral matter. Though the protein content is lower than in fish meal, the protein is apparently

of good quality. Because of the very high percentage of mineral matter, it is best to use shrimp meal in combination with other protein supplements.

Shrimp meal is a satisfactory protein supplement for swine, and especially good results were secured in Louisiana and Mississippi experiments with combinations of half shrimp meal and half soybean oil meal or cottonseed meal.[70] Shrimp meal is also a good protein supplement for poultry rations, particularly when used in combination with other protein supplements.[71]

For dairy cows shrimp meal was a satisfactory substitute for cottonseed meal in Louisiana tests.[72] When the shrimp meal was gradually introduced into the ration, mixtures containing 10 to 19 per cent shrimp meal were readily eaten.

926. Shark meal.—Shark meal apparently differs widely in value, depending on the quality of the raw material and the method used in manufacture. In Florida trials shark meal, having an average of 78 per cent protein, was a satisfactory protein supplement for pigs and for dairy calves, but in tests with chicks the results differed widely.[73]

In Washington experiments dry-rendered meals made from dogfish (a small kind of shark) were of low value for poultry, while wet-rendered dogfish meal gave better results.[74] In shark meal an appreciable part of the nitrogen is in the form of urea, which is valueless for swine and poultry. (129)

927. Starfish meal.—Starfish meal, having about the same content of protein and mineral matter as crab meal, can be made from the entire starfish.[75] This may be used for poultry in the same manner as crab meal. Starfish are a serious problem in the oyster industry, as they eat the young oysters.

928. Whale meal; whale solubles.—*Whale meal,* similar in composition and value to tankage or meat scrap, is made from the clean, undecomposed flesh of whales, most of the fat being expressed.[76] The protein and mineral matter content will vary considerably, depending on the proportion of bone present. Some whale meal has not been of satisfactory quality for feeding, because of decomposition before the material was processed or the use of unsatisfactory methods of preparation.

Whale solubles, somewhat similar to condensed fish solubles or homogenized condensed fish in composition, were satisfactory in Australian tests when supplying most of the animal protein in a poultry ration.[77]

III. Sugar-Factory By-products

929. Cane molasses.—Cane molasses for feeding, also called "blackstrap" or "feeding cane molasses," is a by-product in the manufacture of sugar from sugar cane. It is the residual molasses remaining after as much sugar as possible has been crystallized from the juice which has been purified and then condensed by evaporation. The other by-products from sugar cane are the sugar cane tops and the bagasse. These are sometimes used for stock feeding, as has been pointed out in Chapter XVIII.

In addition to the quantity of cane molasses produced in our southern states, a large amount is brought into this country from other regions making sugar from cane. Only about 10 per cent of the cane molasses that is used for feeding is purchased as molasses by stockmen. The rest is used in the manufacture of formula feeds (commercial mixed feeds). A greater amount of cane molasses is utilized for the production of alcohol, yeast, and other fermentation products than is used for feeding.

Cane molasses is much relished by stock, and it also has a mild laxative effect that is beneficial when the other feeds are constipating. Cane molasses usually has about 55 per cent of sugars, which furnish most of the feeding value.

The usual kind of cane molasses has only 3.0 per cent protein, and this consists largely of compounds having low nutritive value. Also, when any considerable amount of molasses or sugar in other forms is added to a ration for cattle or sheep, the digestibility of the protein and other nutrients of the ration is apt to be decreased. (103) As a result, cane molasses has, on the average, a negative value for digestibility of protein, and in Appendix Table I is rated as supplying no digestible protein. Because of these conditions, it is important that ample protein be furnished by the rest of the ration when large amounts of molasses are fed.

Molasses made from sugar cane grown on muck soil high in nitrogen, as in drained areas of the Florida Ever-

blades, may have 9 per cent of crude protein.[78]

The digestibility of the protein or other nutrients in a ration is usually not decreased when only a small amount of molasses is added to a well-balanced ration. Thus, in Missouri trials the digestibility was increased, rather than decreased, when not more than 2 lbs. of molasses per head daily was added to a dairy ration.[79] In a New York trial there was no decrease in digestibility of protein when one-fourth of the corn in a ration for dairy heifers was replaced by molasses, but a larger proportion of molasses caused a decrease.[80]

Chiefly because cane molasses has an average of 26.6 per cent water, it supplies but 53.6 lbs. total digestible nutrients per 100 lbs., which is only two-thirds as much as in corn grain. Cane molasses weighs about 11.7 lbs. per gallon, and therefore approximately 171 gallons make a ton.

Cane molasses is rich in niacin and pantothenic acid, but is low in thiamine and riboflavin. It has little or no vitamin A or vitamin D.

Molasses has the highest value per pound when a small amount is used to induce stock to eat roughage of rather poor quality with less waste of the stems and coarser parts than there would be otherwise. For this purpose it is often diluted with 1 to 2 parts of water and sprinkled over the roughage. When thus fed, molasses may be worth fully as much or even more than corn or other grain. When molasses is added to a ration made up of feeds that are all palatable, it is generally worth considerably less per 100 lbs. than corn or other grain. This is because it supplies only about two-thirds as much total digestible nutrients per pound as does grain.

Cane molasses is fed most commonly to dairy cows, beef cattle, sheep, and horses, but may be also fed in limited amounts to swine and poultry.[81] When molasses is very cheap, it is sometimes self-fed, especially to fattening cattle.

Cane molasses is used in many formula feeds, or commercial mixed feeds, especially those for cattle and horses. It not only adds to the palatability of the feeds, but it is also often one of the cheapest sources of carbohydrates for the

MOLASSES IS A POPULAR INGREDIENT OF MIXED FEEDS

About 90 per cent of the cane molasses that is fed to livestock in this country is used in the manufacture of formula feeds, or commercial mixed feeds. These fattening cattle are eating a formula feed containing molasses.

feed manufacturer, who can use it in tank-car lots. Molasses is a good dust inhibitor in ground mixtures, and it is a good binder in making pelleted feeds.

When molasses must be shipped in barrels, the cost is much greater than in tank cars. It is therefore frequently expensive for the individual farmer, though it may be cheap at a central feed-mixing plant. Farmers who desire to secure molasses as cheaply as possible should cooperate in arranging with their local feed dealer to order a tank car of molasses. It can readily be hauled direct from the car to the farms in whatever containers may be available, such as well-cleaned, second-hand oil drums. In cold weather it may be necessary to warm the molasses by passing steam through the coils in the tank car, so the molasses will flow satisfactorily.

930. Beet molasses.—In making sugar from sugar beets, the beets are washed and cut into thin strips. Next the juice is thoroughly extracted by means of warm water, leaving the by-product known as wet beet pulp, which is discussed later. After the juice is purified it is evaporated until the sugar crystallizes, and the sugar is separated from the residual molasses by centrifuges. This beet molasses still contains a large amount of sugar, along with mineral salts and other constituents.

Most of the beet molasses is treated further in the Steffen's process to recover more sugar. Some is treated in both the Steffen's process and also in the barium, or Johnstown, process to secure still more sugar. The residual molasses remaining from these processes contains about as much nutrients as untreated beet molasses and has a similar feeding value.

In the barium process, molasses is produced at two stages in the process. These, called A and B molasses, are combined for livestock feeding as C molasses.[82] Some of the A molasses or other beet molasses is processed to separate glutamic acid or sodium glutamate, used for human food flavor enhancement. A by-product from this process, called condensed beet solubles product, or MC 47, is used for feeding. (940)

Beet molasses has as much sugar as cane molasses and is considerably higher in crude protein, but much of this consists of simpler compounds than protein. Beet molasses and beet pulp are very low in phosphorus. When these beet by-products form any large part of the ration, it is therefore necessary to feed a phosphorus supplement.[83]

When properly used, beet molasses has fully as high a feeding value as cane molasses. However, it is much more laxative than cane molasses, on account of the high content of certain alkaline salts and other laxative substances. Stock should therefore be accustomed to beet molasses gradually, and the amounts fed should be strictly limited.

The maximum amounts of beet molasses advised by various authorities for animals accustomed to the feed are as follows, daily *per 1,000 lbs. live weight:* Dairy cows, 2.5 to 3 lbs.; fattening cattle, 4 to 5 lbs.; fattening sheep, 3 to 5 lbs.; driving horses, 2.5 lbs.; draft horses, up to 4 lbs. or even more; and fattening swine, 5 to 10 lbs. Breeding animals should be given smaller allowances than those being fattened, and the amount should be materially reduced 6 weeks before the young are born. As in the case of cane molasses, beet molasses is used in various mixed feeds, especially in alfalfa-molasses feeds. Much of the beet molasses is used in producing dried molasses-beet pulp. (938)

931. Cane molasses; beet molasses for dairy cattle.—When molasses is added to a good dairy ration made up of palatable feeds, it is usually worth somewhat less than corn, pound for pound, but under special conditions the value may be higher. In two Wisconsin trials when 10 per cent of cane molasses was added to a mixture of palatable concentrates, the milk production was practically the same as on the mixture without molasses. In these trials the molasses was worth 89 per cent as much per pound as ground corn.[84]

When a larger proportion of molasses is fed dairy cows, the value of the molasses is apparently much lower. In a New Jersey experiment the milk and fat

yields of cows were markedly reduced when molasses replaced one-half the total digestible nutrients in the grain in the check mixture.[85]

In a New York trial with growing dairy heifers fed good hay or such hay and corn silage, up to 6 lbs. of molasses per head daily produced satisfactory gains, when the amount of protein supplement was increased to make good the lack of protein in cane molasses.[86] The molasses replaced two-thirds the weight of corn, corresponding to the difference in total digestible nutrients.

In the New York trials the gains were much poorer on a ration of low-quality, late-cut hay, molasses, and soybean oil meal, than when corn replaced the molasses on an equal total digestible nutrient basis. Very unsatisfactory results were secured on a ration of the poor hay, molasses, and urea, but they were somewhat better when corn replaced part of the molasses. (129)

Chiefly because of the palatability and appetizing effect of molasses, a considerable proportion of the formula, or mixed, dairy feeds contain 5 to 10 per cent of molasses or more. Feeding much molasses to young calves is apt to cause scours.

To induce cows on official test to consume more feed, molasses is frequently added to their rations, often being added to the water in which dried beet pulp is soaked. In trials by the United States Department of Agriculture with cows heavily fed on official test, molasses thus added to a good ration containing corn silage and legume hay slightly increased the consumption of feed and the production of milk.[87] Except from the standpoint of the value of the increased records, the feeding of molasses was not economical.

In sugar-cane growing regions, cane molasses is often so cheap that it is an economical substitute for part of the grain for dairy cows or heifers. In Hawaiian experiments during 7 years it satisfactorily replaced one-quarter of the concentrates usually fed dairy cows.[88]

DAIRY HEIFER BARN AT CORNELL UNIVERSITY

Experiments to determine the value of cane molasses for dairy heifers were conducted with these heifers. (From New York State College of Agriculture, Cornell University.)

Though some Hawaiian dairymen believed that the continued feeding of considerable amounts of molasses would injure the breeding efficiency of the cows, there was no such effect.

Beet molasses is equal to cane molasses in value for dairy cows, except that too much must not be fed, because of its laxative effect.

932. Cane molasses; beet molasses for beef cattle.—In sugar-cane growing districts cane molasses is widely used for beef cattle, as it is often decidedly lower in price per ton than grain. Also, in other parts of the United States cane molasses shipped in tank cars has often been much cheaper than grain during recent years.

Under such conditions cane molasses is an economical substitute for part of the grain in rations for beef cattle. In the sugar-beet districts of the western states beet molasses is a popular feed for fattening cattle. When not fed in excessive amounts, beet molasses is worth about as much per ton as cane molasses for beef cattle.[89]

Molasses is included in a large proportion of the formula feeds, or commercial mixed feeds for beef cattle, because of its palatability and the prevention of dustiness.

The best results are generally secured when molasses replaces not more than about one-half of the concentrates usually fed, and one should be sure that the ration provides plenty of protein.

If the roughage is of poor quality, sprinkling diluted molasses over it will frequently induce cattle to eat more of it than otherwise. Adding a small amount of molasses to a ration with poor roughage for fattening cattle may be beneficial, even if the molasses is not fed on the roughage. For example, in 3 Ohio experiments the gain of fattening steers was increased an average of 0.29 lb. by the addition of 1 lb. cane molasses to a full feed of corn-and-cob meal, fed with 1.5 lbs. soybean oil meal and with late-cut, weathered timothy hay for roughage.[90] Thus fed, the molasses was worth more than corn-and-cob meal per pound. Differing from these results, in a Texas trial the gain of fattening cattle was slightly reduced by feeding 2 lbs. of cane molasses in place of 1.5 lbs. milo grain in a ration of ground milo, cottonseed meal, and only cottonseed hulls or ground cotton gin trash for roughage.[91] In this trial the molasses had a very low value.

In southern experiments cane molasses has had a somewhat higher value for fattening cattle than indicated by its total digestible nutrient content when added to such a ration as cottonseed meal with hay, silage, or silage and hay for roughage. In 12 such experiments the addition of 3.5 lbs. of molasses per head daily increased the average daily gains 0.18 lb., and 100 lbs. of molasses replaced an average of 20 lbs. cottonseed meal, plus 88 lbs. hay and 79 lbs. silage.[92]

When cane molasses is cheap, sometimes it is self-fed to fattening cattle on pasture. Better gains are produced and the molasses has a higher value, when it is fed along with some grain than when molasses alone is fed. For example, in 3 New York trials yearling steers self-fed cane molasses alone on good pasture ate an average of 11.2 lbs. molasses a day and gained 1.6 lbs., in comparison with 2.4 lbs. for others full-fed ground corn, and eating 12.9 lbs. corn a day.[93] Other steers fed 6.3 lbs. of corn a day and self-fed molasses in addition gained 2.1 lbs. a day.

When fed in combination with corn, molasses was worth 72 per cent as much as corn per pound, but when it was the only concentrate its value was only 50 per cent of that of corn.

In Florida trials cane molasses has been compared to ground snapped corn, including the husks, for fattening steers on excellent pasture on drained land in the Everglades.[94] Fair gains were made by cattle self-fed molasses on such pasture and the molasses was worth about 80 per cent as much as ground snapped corn.

In 7 Nebraska experiments with beef calves wintered on corn silage, protein supplement, and a small amount of corn grain, the rate of gain was the same

when 1 lb. of cane molasses was substituted for 0.7 lb. of the corn grain.[95]

When beet molasses is substituted for part of the grain in rations for fattening cattle, it is usually worth somewhat less per ton than grain. In such experiments the value of beet molasses has ranged from 75 to about 100 per cent of that of grain.[96]

933. Adding molasses to an excellent ration.—Cattle feeders have been much interested in knowing definitely whether or not it would pay to add a small amount of molasses to an already excellent ration for fattening cattle, such as grain, legume hay, corn silage, and protein supplement. The statement is sometimes made that the addition of molasses will appreciably increase the gains and the selling price of the cattle, and that molasses, thus fed, will be worth more per ton than corn.

Many experiments have been conducted to determine the effect of adding cane molasses to well-balanced rations made up of palatable feeds. In 29 trials the addition of an average of 2.2 lbs. cane molasses per head daily to an excellent ration has made only a trifling increase in the rate of gain (an increase of only 0.04 lb. per head daily.) [97] The molasses-fed cattle sold for a slightly lower average price than the others, and they required more concentrates for 100 lbs. gain. Considering all factors, cane molasses was actually worth only 54 per cent as much per ton as grain in these many experiments.

The results have been similar when larger amounts of molasses have been added to rations made up of palatable feeds, or when molasses has been thoroughly mixed with chopped hay or other feeds. Even when molasses has been added to a palatable ration during only the latter part of the fattening period, there has been no advantage from such use.

These numerous experiments show definitely that there is no advantage in adding cane molasses to a palatable ration for fattening cattle, unless the cost of molasses is much less per ton than that of grain. It must be borne in mind that the no-molasses rations in these trials were generally made up of feeds of high quality and that the feeding was done by experienced stockmen. Under less favorable conditions it seems probable that the value of cane molasses in comparison with grain would at least be proportional to the amount of digestible nutrients supplied. This is 67 per cent of the amount furnished by No. 2 grade dent corn.

Molasses seems to have the highest value per ton when added to such a ration as cottonseed meal and cottonseed hulls or other rather low-grade roughage, and less value when added to a ration containing a large amount of silage.

934. Cane molasses; beet molasses for sheep.—Cane molasses or beet molasses is sometimes added to the rations of sheep, especially fattening lambs. Molasses has the highest value in a fattening ration if not more than one-third to one-half pound is fed per head daily. This serves as an appetizer and usually increases the gains slightly. Molasses does not produce satisfactory gains if used as the entire substitute for grain.

When replacing part of the grain for fattening lambs in a ration made up of palatable feeds, molasses is usually worth somewhat less than corn or other grain, because of the lower content of digestible nutrients. If a small amount of molasses is fed as an appetizer or to get lambs to clean up rather inferior hay or other dry roughage, it may be worth fully as much as grain per pound.[98] Cane molasses and beet molasses probably have about the same value for sheep, when containing equal percentages of sugar.[99]

In feeding molasses to sheep, it is usually poured in the grain troughs as a broad "ribbon" or is mixed thoroughly with chopped hay or other roughage. Care must be taken that the wool does not become smeared with molasses.

In Wisconsin experiments lambs fed a concentrate mixture containing 10 per cent cane molasses gained a trifle more than others fed a similar mixture having no molasses.[100] However, in producing gain in weight the value of the molasses was much lower than that of corn. Similarly, in North Dakota trials cane mo-

lasses had a much lower value per pound than corn when 10.5 per cent of molasses was added to rations for fattening lambs.[101]

The value of beet molasses for fattening lambs is shown by the results of 20 trials in each of which one lot of lambs was full fed a good ration without molasses and another lot received molasses in addition.[102] The addition of 0.32 lb. molasses per head daily increased the gain a trifle on the average, and each 100 lbs. of molasses saved 63 lbs. grain or other concentrates and 30 lbs. of hay or hay equivalent in other roughage. With feeds at representative prices, 100 lbs. of molasses were equal to about 78 lbs. of grain, not considering the slight advantage in rate of gain.

935. Molasses for horses and mules.—Molasses is well liked by horses and mules, and they are sometimes fed a quart or so a day as an appetizer or conditioner, even when molasses is higher in price than grain. Diluted molasses may be sprinkled over rather coarse or unpalatable hay so that it will be cleaned up better.

In sugar-cane regions cane molasses is often the most economical source of carbohydrates for work animals. The molasses is usually mixed with other feeds, but is sometimes fed in troughs. As much as 9 lbs. per head daily of cane molasses were fed to mules in Louisiana tests to replace much of the grain.[103] However, such a heavy allowance tended to increase sweating and "winding" in hot weather. When fed as a partial substitute for grain, molasses was about equal to corn in value per pound. Mules fed only molasses and chopped hay, without grain, were not able to do heavy work in hot weather.

Beet molasses can likewise be used for horses and mules, but it should not be fed in excess because of its very laxative nature. In trials with 130 hard-worked horses of a Budapest transportation company, good results were obtained with a ration, per 1,000 lbs. live weight, of 4.1 lbs. beet molasses mixed with 5.6 lbs. wheat bran and fed with 5.7 lbs. corn and an unlimited allowance of hay.[104] One pound of molasses replaced 0.78 lb. of corn.

936. Molasses for swine.—Molasses, either cane or beet, is used much less commonly for swine than for cattle, sheep, or horses. However, when considerably cheaper than corn or other grain, it can be substituted for a part of the grain. A small percentage of molasses is often included in formula, or mixed, commercial supplements and other formula swine feeds as a binder, to prevent waste in feeding.

Too much molasses causes scours in young pigs. However, in Hawaiian tests as much as 20 per cent of cane molasses was satisfactory for pigs from weaning up to 70 lbs. in weight, if it was introduced gradually into the feed mixture.[105] Thus fed, the value of the molasses per pound was about two-thirds that of grain, and molasses was economical in Hawaii, where it is very cheap.

For older pigs molasses can form a larger proportion of the ration. However, the rate of gain is usually less on rations containing 10 per cent or more of molasses than on rations without molasses. In several experiments in which 10 to 20 per cent or more of molasses has been added to good rations for well-grown pigs, the results have varied widely.[106] In some tests molasses has been worth from 70 to 84 per cent as much as grain, but in more of the experiments it has had an exceedingly low value. It is not therefore wise to include any appreciable amount of cane molasses in swine rations unless its cost is far below that of grain.

Beet molasses is apt to cause scours in pigs unless they are started on it very gradually and only limited amounts are fed. In Utah experiments adding as little as 15 per cent of beet molasses to the ration of young pigs produced a serious nutritional disease.[107] The pigs not only failed to grow but had a staggering gait and often died. Supplementing such a ration with green alfalfa or with 5 per cent of brewers' dried yeast prevented the trouble. Hogs weighing 100 lbs. or more at the start were fed as much as 40 per cent of beet molasses without injury, even without these supplements.

937. Molasses for poultry.—Molasses is not commonly used for poultry, but 2 to 5 per cent of cane molasses is often included in formula, or mixed, poultry mashes. Too much molasses in a poultry ration makes it too laxative. The best results are usually secured with not over 2.5 per cent of molasses, though 5 or 6 per cent is sometimes used in an all-mash ration, or 10 per cent in a mash fed with scratch grain.[108]

In trials in Hawaii, where cane molasses is very cheap, as much as 33 per cent of molasses was economical in rations for chicks, 18 per cent for cockerels, and 35 per cent of a mixture of 5 parts molasses and 1 part sugar cane bagasse pith for layers, although the feed efficiency was lowered considerably with so much molasses.[109]

938. Molasses feeds; alfalfa-molasses feeds.—Cane molasses or beet molasses is used as an ingredient in many of the formula feeds, or commercial mixed feeds, on the market, especially those for dairy cattle, beef cattle, and horses. Molasses is added to high-grade mixed feeds on account of its palatability, because it prevents dustiness, and also because it is often one of the cheapest sources of readily digested carbohydrates. Many experienced dairymen prefer a high-grade mixture containing molasses to one made of the same ingredients, except without molasses.

In lower-grade mixed feeds, molasses has a special value, as it aids in making a mixture palatable that might otherwise not be liked by stock. Unfortunately, molasses also tends to mask the presence of low-grade ingredients, and therefore may make a trashy feed appear much more valuable than it really is. From the list of guaranteed ingredients and the guarantees for protein, fat, and fiber, one can usually determine approximately the relative value of any particular mixed feed.

In several experiments at corn-belt stations with fattening cattle, rations including various brands of commercial molasses feeds have been compared with such standard rations as corn grain, corn silage, legume hay, and a small amount of linseed meal or cottonseed meal.[110] In nearly all of these tests the gain was lower instead of higher on the molasses feed, and the profit was less than on the standard rations. These trials show that in the commercial fattening of cattle in the corn belt, corn grain must commonly be used as largely as possible, in order to secure the greatest net returns.

In a Michigan test with fattening cattle, two brands of commercial molasses feeds consisting chiefly of cane molasses, crushed oats, cracked corn, and alfalfa meal, had no appreciable advantage over a mixture of crushed oats and cracked corn, and the latter was cheaper.[111] The molasses feeds sometimes became sour or caked in the sacks.

In the western alfalfa districts a considerable amount of *alfalfa-molasses feeds* is manufactured. These consist of combinations of alfalfa meal with various percentages of beet or cane molasses. Usually such feeds contain 20 to 40 per cent of molasses.

Alfalfa-molasses feeds are palatable to stock and can be used to replace a limited amount of the grain in the ration of dairy cows, beef cattle, and sheep. It must be borne in mind, however, that such feeds are more like a roughage than like a concentrate. Therefore, when any considerable amount is fed to fattening cattle or sheep, the value of the alfalfa-molasses feed is much below that of grain, and not greatly different from that of alfalfa hay.[112] Sometimes alfalfa-molasses feeds are unwisely used as a substitute for such protein supplements as linseed meal or cottonseed meal. They are not high in protein, and therefore should be used as a substitute for part of the grain, and not as a protein supplement.

Molassine meal, sometimes made in Europe by mixing molasses with peat or sphagnum moss, has occasionally been imported into the United States. Peat has no nutritive value and the moss is also of very low worth, though arctic animals live on it to some extent. Practically the only nutrients in molassine meal are in the molasses, and at the prices usually

asked it has been a very uneconomical purchase.[113]

939. Dried molasses mixtures.—Molasses can be dried to form a dry meal, but such a product absorbs so much moisture on exposure to the air that it soon becomes sticky. It must therefore be shipped in moisture-proof bags, and speedily mixed with other ingredients.

Various dry mixtures of molasses and absorbent feeds, such as ground light-weight grain screenings, brewers' dried grains, or corn oil meal, are marketed, which are free-flowing and do not cake. Some such products apparently have a much lower percentage of molasses equivalent than is indicated by the claims made for them, judging by the fiber content. Others may have the equivalent of 45 per cent or more of molasses.

The actual economy of such products can be estimated from the guaranteed composition and ingredients, especially from the fiber guarantee.

940. Condensed beet solubles product.—This feed, also called MC 47, is the condensed residue obtained in the separation of glutamic acid from beet molasses or the Steffen's filtrate in beet sugar production. It has about 64 per cent dry matter, 20 per cent crude protein, and 18 per cent mineral matter. It is very high in betaine, which can partially replace choline in the diet, and is therefore useful in certain poultry rations.[114] (218)

In California experiments it furnished 80 per cent as much digestible nutrients as average cane molasses.[115] A concentrate mixture or ground hay with 10 per cent of this product added was readily eaten by dairy cows after the second feeding of the mixture, and mixtures containing it were satisfactory for steers or lambs.

941. Sugar.—Though the nutritive value of sugar is no greater than that of an equal weight of starch, the great fondness for it shown by stock makes it helpful in some cases for stimulating the appetite. For this reason, a small amount is sometimes added to concentrate mixtures used in fitting animals for show. Also, as shown in Chapter XXXV, the consumption of pig starters or mixtures for creep-feeding suckling pigs may be increased by including 5 to 20 per cent of cane sugar in the mixture.

Experiments were conducted by the Hawaiian Station to find to what extent low-grade sugar could be substituted for imported grain in poultry rations, if imports were cut off at any time.[116] Because of the sticky nature of this sugar, which contains considerable molasses, it was usually mixed with 10 to 20 per cent of ground sugar-cane bagasse pith. The results were satisfactory when such a mixture formed as much as 35 per cent of the ration for hens and 40 per cent for chicks, the protein content being adjusted properly.

In another Hawaiian trial the addition of 5 per cent of cane sugar to a ration for pigs increased the feed consumption and produced slightly more rapid gains.[117] In a Kansas test there was no advantage in adding 0.5 lb. of sugar per head daily to a ration for horses.[118]

In a recent Utah experiment the feeding of cane sugar to beef cattle and pigs for about 3 days before slaughter tended to improve slightly the dressing percentage and also the flavor of the livers.[119]

942. Dried beet pulp; dried molasses-beet pulp.—Most of the beet pulp produced in this country is dried at the beet-sugar factories to form *dried beet pulp*, or is combined with molasses and dried to form *dried molasses-beet pulp*. These feeds are palatable, bulky, slightly laxative, and keep well in storage.

Dried beet pulp and dried molasses-beet pulp are rich in carbohydrates, but they are relatively low in protein and poor in fat. Dried beet pulp has an average of 8.8 per cent protein, 0.6 per cent fat, 19.6 per cent fiber, and 58.7 per cent nitrogen-free extract. Though it is high in fiber for a concentrate, the fiber is well digested, and dried beet pulp has 68.7 per cent of total digestible nutrients, which is nearly as much as in oats.

Dried molasses-beet pulp is slightly higher in protein and nitrogen-free extract and somewhat lower in fiber than is dried beet pulp. However its feeding value is approximately the same.

Both dried beet pulp and dried molasses-beet pulp have a fair amount of calcium, but they are very low in phosphorus. When a considerable amount of either of these feeds is used, it may therefore be necessary to add a phosphorus supplement to the ration.

Dried beet pulp is fair in niacin content, but is low in other B-complex vitamins. It does not supply carotene or vitamin D.

Largely because of the bulky nature and the palatability, dried beet pulp and dried molasses-beet pulp are very popular feeds for dairy cattle, and most of the supply is used for this purpose. These feeds are also used extensively in the sugar-beet districts as a substitute for part of the grain in fattening cattle or sheep and may replace part of the grain for horses.

By rolling dried molasses-beet pulp through corrugated rollers, the bulk can be reduced and the feed can be mixed more readily with grain. Molasses-beet pulp pellets are also made, which weigh about 4 times as much per bushel as ordinary dried molasses-beet pulp. These eliminate loss from blowing when fed in the open.

943. Dried beet pulp; dried molasses-beet pulp for dairy cattle.—As a source of nutrients for economical milk production, these bulky, palatable feeds are worth no more than ground corn or oats, or even less.[120] However, as a part of the concentrates for cows on official test, or when a limited amount is added to a heavy concentrate mixture to supply bulk, they may be worth more than grain. Cows on official test are often fed 6 to 10 lbs. of dried beet pulp per head daily, well soaked from one feeding to the next with water to which molasses is sometimes added.

When silage or other succulent feed is not available, dried beet pulp, soaked before feeding, is occasionally used as a substitute, though it is usually more expensive than silage.[121] If cows are provided with water in drinking cups, the results are probably just as good when dried beet pulp, up to an allowance of 8 lbs. per cow daily, is fed dry as when it is soaked.[122]

Both dried beet pulp and dried molasses-beet pulp are too bulky and too low in digestible nutrients to be very efficient as the only concentrate for good dairy cows. They have a considerably higher value when mixed with more concentrated feeds.[123]

944. Dried beet pulp; dried molasses-beet pulp for other stock.—When cheaper per ton than grain, these feeds are economical substitutes for not over one-half the grain in rations for fattening cattle or lambs. Thus used, they produce good gains and have a high feeding value. Adding these bulky feeds to a fattening ration helps to keep the animals on full feed without digestive disturbances, and tends to reduce trouble from bloat on such a ration as ground barley and alfalfa hay.

In results of experiment station trials compiled by the author, these feeds have, on the average, been about equal to barley or grain sorghum in value per ton, when replacing not more than one-half the grain in rations for fattening cattle or lambs.[124] Maynard of the Great Western Sugar Co. states that in 46 experiment station trials with fattening cattle or lambs, a ton of dried molasses-beet pulp replaced an average of 1,782 lbs. grain and 836 lbs. alfalfa hay.[125] Harris of the Holly Sugar Corporation, from a study of 51 trials by experiment stations and beet sugar companies, has computed that dried molasses-beet pulp has a net-energy value higher than corn grain, when fed as a substitute for part of the grain in rations for fattening cattle or lambs.[126]

These beet by-products even give fair to good results as the only concentrate for fattening lambs, when fed with alfalfa hay. Thus fed in 18 trials, dried molasses-beet pulp was worth about 80 per cent as much as corn.[127] Dried beet pulp or dried molasses-beet pulp can also be used as a substitute for grain in wintering breeding ewes or beef cattle.[128]

Dried beet pulp is not well liked by horses, but when mixed with other concentrates it is satisfactory when forming not over one-third of the concentrate allowance.

These beet by-products are too bulky to have much usefulness for swine or poultry.[129] However, in English tests pigs weighing 60 lbs. or over made fair gains when dried beet pulp or molasses-beet pulp replaced part of the grain in the ration.[130]

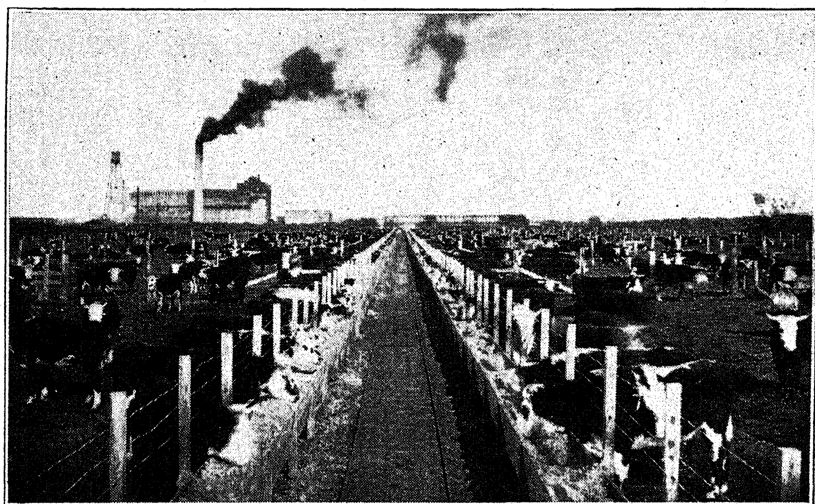
945. Wet beet pulp.—The wet pulp that is not dried to make dried beet pulp is usually stored at the beet-sugar factories

in huge open silos, which are merely paved areas with strong walls. Here the pulp undergoes an acid fermentation similar to that which occurs in corn silage. It is then hauled to the farms where it is fed, at intervals frequent enough to prevent spoilage. Sometimes the fresh pulp is hauled to the farms and stored in ordinary silos or else in trench or pit silos.

Ensiled pulp keeps much better than fresh pulp when exposed to the air, and it is therefore preferred for feeding. Owing both to the draining away of water and to the loss of nutrients in the fermentation, there will be a shrinkage in weight of about 30 per cent when the pulp is ensiled in a trench silo.[131]

Wet beet pulp is very watery and contains an average of only 11.6 per cent dry matter. Even pulp that has been pressed at the factory to remove some of the water has only about 14 per cent dry matter. The chief value of wet beet pulp is in the carbohydrates it contains. Though most of the sugar has been extracted, the fiber and nitrogen-free extract of wet beet pulp are well digested by cattle and sheep. The dry matter in wet beet pulp is about equal to that of roots in feeding value.

Beet pulp is low in protein and especially low in phosphorus. When heavy allowances of pulp are fed, these deficiencies must be corrected. In the West wet beet pulp is generally fed with alfalfa hay, which largely or entirely makes good the lack of protein and is usually fair in phosphorus content. However, Utah experiments show that dairy cows or fattening stock may suffer seriously from phosphorus deficiency when fed rations made up largely of wet beet pulp and alfalfa hay without a phosphorus supplement.[132] To guard against a lack of phosphorus, steamed bone meal or some other safe phosphorus supplement should therefore be added to such rations. When a phosphorus-rich protein supplement is fed, such as cottonseed meal, linseed meal, or wheat bran, it may supply enough of this mineral.



Fattening Steers on Beet Pulp in the West

In the vicinity of the beet sugar factories thousands of cattle are fattened on wet beet pulp and other feeds. In the feed lots shown in this view the beet pulp is brought from the beet sugar factory on the tramway.

Wet beet pulp is fed chiefly to fattening cattle or lambs or to dairy cattle. In limited amounts it is satisfactory for idle horses and can even be fed to swine as a substitute for a part of the grain.[133]

Stock should be accustomed to the pulp gradually, but later cattle and sheep may be allowed all they will clean up, if there is a plentiful supply.

946. Wet beet pulp for dairy cows.—Wet beet pulp is liked by dairy cows and produces milk of good quality when fed under proper conditions and not in excess. In Utah trials cows fed wet beet pulp as a substitute for corn silage produced fully as much milk as those fed corn silage.[134]

Because of the much lower dry matter content of wet beet pulp, it required 2.1 lbs. of it to replace 1 lb. of corn silage. Per pound of dry matter, the pulp was worth slightly more than corn silage. To avoid any danger of injuring the flavor of the milk, wet beet pulp should be fed after milking and in a sanitary manner, the same as in the case of silage.

947. Wet beet pulp for beef cattle and sheep.—In the vicinity of the western beet-sugar factories large numbers of cattle and sheep are fattened on wet beet pulp. This is usually fed with alfalfa hay, which makes good the low protein content of the pulp. If a liberal amount of alfalfa hay is not supplied, a sufficient amount of protein supplement should be fed to balance the ration.

Often cattle are fed only wet beet pulp and alfalfa hay for the first part of the fattening period and then a limited amount of grain or other concentrates is added during the latter part. Sometimes cattle are fattened on only wet beet pulp and alfalfa hay, but the gains are much slower than when a limited amount of concentrates is fed, and also the cattle do not reach as good a finish.

When beet pulp and beet molasses form a large part of the rations, a deficiency of phosphorus must be guarded against. The importance of this is shown in 3 Utah experiments in which steers gained only 1.07 lbs. per head daily on the average when fed only wet beet pulp, beet molasses, and all the alfalfa hay they would eat.[135] Adding 0.1 lb. of bone meal daily to this ration doubled the gains and reduced the feed cost per 100 lbs. gain by 44 per cent.

When a sufficient amount of wet beet pulp is available, fattening cattle are often fed 60 lbs. or more per head daily and fattening lambs 5 lbs. or more.[125] When wet beet pulp is fed along with grain and hay, 100 lbs. of dry matter in the pulp have a higher value than the same amount of dry matter in dried beet pulp.

In 4 Colorado trials with fattening calves the addition of wet beet pulp to a ration of ground barley, alfalfa hay, and 1.0 lb. cottonseed cake slightly increased the rate of gain.[136] Each ton of wet beet pulp was equal to 145 lbs. of concentrates and 342 lbs. of alfalfa hay, without considering the more rapid gain and slightly better finish of the cattle. In 2 Oregon trials, the gain of fattening yearlings was increased by adding wet beet pulp to a ration of corn and alfalfa hay, but each ton of beet pulp saved only 36 lbs. corn plus 382 lbs. hay.[137]

In 32 similar experiments with fattening lambs, the addition of wet beet pulp to a ration of grain and alfalfa hay has likewise usually increased the gains slightly.[138] In these experiments 1 ton of wet beet pulp replaced 129 lbs. of grain plus 376 lbs. of hay. Wet beet pulp is especially suitable for fattening aged ewes with poor teeth. In feeding heavy allowances of the watery pulp, it is important that the yards be kept dry by proper drainage and the use of bedding.

Because of the low content of dry matter, it usually requires nearly 2 tons of wet beet pulp to replace a ton of corn silage for fattening cattle or sheep. In 9 experiments with fattening cattle the gain has been a little more rapid on a ration of wet beet pulp, alfalfa hay, and concentrates than when corn silage replaced the pulp.[139] Each ton of siloed wet beet pulp replaced 1,017 lbs. silage, plus 24 lbs. concentrates and 13 lbs. hay.

IV. Distillery and Fermentation By-products

948. Distillery by-products.—In the manufacture of distilled liquors and alcohol from grain, the grain is first ground and cooked with water. Then after cooling, malt is added, to furnish amylase, or diastase, the starch-digesting enzyme, or else an amylase-containing product produced by fermentation, called "fungal amylase," is added.

The mixture, called mash, is held at the proper temperature for the amylase to change the starch into sugar. In the next stage of the process the sugar in the watery mash is converted into alcohol by the action of yeast. After the fermentation is completed, the alcohol is distilled off, leaving a watery residue, called *stillage,* or *distillery slop.*

The coarser particles are usually strained out of the stillage, forming *wet distillers grains.* The water-soluble material and the fine particles that pass through form what is known as thin stillage, or thin slop. This may be condensed by evaporation and dried to form *dried distillers solubles.* Sometimes the distillers solubles are marketed in condensed, or semi-solid, form.

The condensed distillers solubles are often added to the wet distillers grains and the mixture then dried, to form *distillers dried grains with solubles,* also called *dark distillers dried grains.* Some-

times the wet distillers grains are dried without adding the distillers solubles. This product is called *distillers dried grains without solubles,* or *light distillers grains.*

949. Distillers dried grains.—Distillers dried grains made from a grain mixture in which corn predominates are called *corn distillers dried grains.* They are high in protein, averaging 26 per cent or more and are also rich in fat, with an average well over 8 per cent. Though they are almost as bulky as wheat bran, they are highly digestible and are as rich as corn grain in total digestible nutrients. *Corn distillers grains without solubles* have 84.0 per cent of total digestible nutrients, on the average.

The chief difference between distillers grains with solubles and the grains without solubles is that the former are very much higher in B-complex vitamins. This higher vitamin content increases their value in poultry rations but is probably not important for cattle or sheep under usual conditions. Distillers grains with solubles are also higher in minerals than the grains without solubles.

Rye distillers dried grains, made from a grain mixture in which rye predominates, are lower in protein than the average for the corn grains. Formerly, the average protein content was only 18.5 per cent and the average fiber content was 15.6 per cent. The value of such rye distillers grains was much lower than of corn distillers grains. Some recent samples of rye distillers dried grains have had an average of 24.4 per cent protein and only 11.5 per cent fiber. Such rye distillers grains more closely approach corn distillers grains in value.

Some grain sorghum and wheat have also been used in the production of alcohol or distilled liquors. *Sorghum distillers dried grains* of high grade, made from a grain mixture in which grain sorghum predominates, resemble corn distillers grain in composition, except that they are lower in fat. Some sorghum distillers grains have been lower in protein and higher in fiber.

During World War II considerable wheat was used in this country in producing alcohol for technical purposes. The *wheat distillers dried grains* which are made when entire wheat grain is processed have about as much protein as do corn distillers grains. When wheat grits are employed, from which most of the bran has been removed, the wheat distillers grains may have 46 per cent protein.

Distillers dried grains made by the fungal-amylase process are about equal to those made by the malt process.[140]

Distillers dried grains are used chiefly for dairy cattle but are also a satisfactory protein supplement for beef cattle or sheep. They have decided limitations as a feed for swine or poultry. Distillers grains are not especially well liked by stock when fed alone, but there is no difficulty when they are used in suitable mixtures.

Occasionally, distillers dried grains are cheaper than corn or other cereal grains. They may then be used as a substitute for part of the grain in feeding dairy cattle, beef cattle, sheep, or horses. They had best form not more than about half of the concentrate mixture for cattle or sheep and not more than one-fourth of the concentrates for horses.

Because of the considerable range in composition of various types of distillers dried grains, they should be bought on a definite guarantee of composition. Some of the distillers dried grains sold as corn distillers grains have not been up to the usual grade for this feed, apparently being made from a mixture containing a large proportion of other grain.

950. Distillers dried grains for dairy cattle.—Corn distillers dried grains are a popular protein supplement for dairy cows and are a favorite ingredient in concentrate mixtures for cows on official test. Because of the high fat content of corn distillers grains, they are especially valuable for milk production when the other feeds in the ration are rather low in fat. (**1020**)

In New York experiments corn distillers grains have been slightly superior to a mixture of corn gluten feed and soybean oil meal for dairy cows, and rye distillers grains having 25 per cent pro-

tein were about equal to corn gluten feed.[141] Sorghum distillers grains with 30 per cent protein also equaled corn distillers grains.

951. Distillers grains for beef cattle.—Distillers dried grains are a satisfactory protein supplement for beef cattle. Because of their lower protein content, it will take about 1.5 lbs. to furnish as much protein as in 1.0 lb. of soybean oil meal or cottonseed meal, but this amount of distillers grains will supply more total digestible nutrients.[142] Corn distillers dried grains have about as much protein and total digestible nutrients as a mixture of half soybean oil meal and half grain or corn-and-cob meal. They were equal to such a mixture in Ohio trials with beef calves being wintered and in a Kentucky trial with beef cows nursing calves in winter.[143] When used as the only protein supplement in rations for fattening cattle, distillers grains may not produce quite as rapid gains as soybean oil meal, linseed meal, or cottonseed meal.

In 3 Kansas tests 4 lbs. of corn distillers grains were worth somewhat more than 2 lbs. cottonseed cake to supplement sorghum grain and sorghum silage for fattening steers.[144] In Kentucky experiments with fattening cattle a mixture of half corn distillers grains and half soybean oil meal produced slightly more rapid gains, on the average, than distillers grains as the only supplement.[145] Replacing half the distillers grains with urea plus sulfur reduced the gains. In Kansas trials corn distillers grains were very slightly superior to sorghum distillers grains for fattening cattle.[144]

Used as a substitute for one-third the corn for fattening cattle in Maryland trials, rye distillers grains were worth 73 per cent as much as No. 2 grade corn.[146]

952. Distillers dried grains for sheep.—Corn distillers grains with solubles produced nearly as good results as did linseed meal as the protein supplement for fattening lambs in 4 New York experiments.[147] Because of the lower protein content of distillers grains, somewhat more was needed to balance the ration, and the distillers grains were worth 91 per cent as much per ton as linseed meal. In one trial corn distillers grains without solubles had a lower value, perhaps due to the use of a considerable proportion of other grains in the manufacture. As a substitute for part of the corn grain, distillers grains were worth slightly more per ton than corn when they replaced one-third the corn, and 100 lbs. were equal to 95 lbs. corn minus 11 lbs. hay when they replaced half the corn.

Rye distillers dried grains were not satisfactory as the only concentrate for wintering breeding ewes in Maryland trials.[148] Death losses and nervous disorders occurred, apparently because of some nutritive deficiency.

953. Distillers grains for swine.—Distillers dried grains are not usually fed to swine, since they are much better suited for feeding cattle, especially dairy cows.[149] They are unsatisfactory as the only protein supplement for pigs not on pasture. Distillers grains produce fair results when replacing not over one-half the tankage or meat scrap in a ration, or when used as the protein supplement for pigs on good pasture. In an Ohio test corn distillers dried grains had a low value when used as a substitute for one-fourth of the corn in a well-balanced ration for pigs not on pasture.[150]

954. Distillers grains for poultry.—Distillers dried grains can be used satisfactorily in rations for poultry, if there is a sufficient amount of such a protein supplement as dried skimmilk, fish meal, or meat scrap, which have protein of better quality.[151] Because of the bulkiness of distillers dried grains, rations for laying hens had best not have more than 10 per cent of distillers grains, and rations for chicks not over 7 or 8 per cent. For poultry, distillers grains with solubles are decidedly preferable to grains without solubles, unless an abundance of riboflavin and other B-complex vitamins is supplied by other feeds.

When corn distillers dried grains are much cheaper than corn, they may

be an economical substitute for one-half of the corn in an all-mash laying ration.[152]

955. Distillers dried solubles.—Distillers dried solubles are used chiefly in formula, or mixed, feeds for poultry, swine, and dairy calves, because of their high content of certain B-complex vitamins. However, the dried solubles may have fully as much protein as do corn distillers dried grains, and they are a satisfactory protein supplement for dairy cows, beef cattle, and sheep.

The protein of distillers solubles is not of high quality for poultry and swine and does not effectively supplement the protein of the cereal grains.[153] Distillers solubles are very rich in niacin and choline and have a good content of riboflavin, pantothenic acid, and thiamin, but they do not have much vitamin B_{12}. They also supply one or more of the unidentified vitamins important in poultry rations.[154]

Molasses distillers dried solubles contain much less protein than the solubles from grain fermentation, having an average of only 12.9 per cent. They have over 24 per cent mineral matter, and hence furnish much less total digestible nutrients than the grain solubles.

Because of the content of B-complex vitamins, 2.5 to 5.0 per cent of distillers solubles is included in many formula poultry feeds. The addition of distillers solubles to a practical ration containing little or no animal protein supplements appreciably increases the rate of growth and the feed efficiency.[155] Not more than 5 to 10 per cent of distillers solubles should generally be used in poultry rations, because of the laxative effect.

For swine, distillers solubles have a distinct value as a source of B-complex vitamins when added to dry-lot rations low in these vitamins. Catron of the Iowa Station has recently summarized the results of 21 experiment station trials in which distillers solubles have been added to various types of rations for growing and fattening pigs, with and without an animal protein supplement.[156] On the average, the addition of distillers solubles increased the daily gain 4.2 per cent and reduced the amount of feed per 100 lbs. gain 3.3 per cent. In 9 of the trials distillers solubles did not increase the gains.

The benefit from adding distillers solubles to such a ration as corn, soybean oil meal, 4 per cent alfalfa meal, and minerals for growing and fattening pigs is shown by 4 Ohio trials.[157] The pigs remained healthier, the daily gain was increased 0.24 lb., and 12 lbs. less feed were required per 100 lbs. gain. Adding distillers solubles to the ration produced about as good results as adding meat scrap.

In Illinois experiments with brood sows and pigs kept continuously in dry lot, without pasture or any green feed, there was a benefit from adding 6 per cent of distillers dried solubles to typical rations that contained no alfalfa meal or not over 5 per cent of alfalfa.[158] Increasing the alfalfa to 15 per cent produced similar improvement.

Wisconsin tests indicate that the addition of extra alfalfa to swine rations fed under restricted dry-lot rations generally produces as good results as adding distillers solubles, and at lower cost.[159] Kentucky and Nebraska experiments show that distillers solubles are not satisfactory as the only protein supplement for pigs, but that they can be used as a substitute for linseed meal or soybean oil meal in trio-type supplemental mixtures.[160]

Distillers dried solubles may be used in dry calf starters or milk replacers as a source of B-complex vitamins. Corn or sorghum distillers solubles have been a satisfactory substitute for dried skimmilk or dried whey and also dried yeast in calf starters where the chief protein supplement was soybean oil meal, which provides excellent protein.[161] There is no advantage in adding distillers solubles to a calf starter that otherwise has ample B-complex vitamins.

Dried distillers solubles are a satisfactory protein supplement for dairy cows or beef cattle, but they do not have the especial value as a source of B-complex vitamins that they have for poultry, pigs, or young dairy calves. In New York trials corn distillers solubles were slightly

superior to corn gluten feed as a protein supplement for dairy cows, but not quite equal to corn distillers dried grains.[162]

In 2 Kentucky trials fattening steers fed corn distillers solubles high in protein as the supplement gained more rapidly than steers fed soybean oil meal as the protein supplement, and they required 7 per cent less feed per 100 lbs. gain.[163] In another trial corn distillers solubles having only 20 per cent protein were much less valuable. Corn distillers solubles were very satisfactory as the protein supplement for wintering stocker steers.

956. Stillage, or distillery slop.—The stillage, or distillery slop, left after the alcohol is distilled from the fermented mash, is sometimes fed to livestock on farms near a distillery. The whole stillage has only 6 to 8 per cent dry matter, and the strained stillage, after the wet distillers grains are removed, about 4 per cent or less.

Stillage has been chiefly used for fattening cattle, which are allowed to drink all of it that they will take. To produce satisfactory results the cattle should also be fed at least 5 lbs. per head daily of hay of reasonably good quality, that will supply considerable vitamin A value. If the stillage comes from grain other than yellow corn, there may be a serious deficiency of vitamin A, unless the hay is of good quality or a vitamin A supplement is fed. It is wise to supply a mineral mixture to furnish additional calcium.

Cattle will make fair gains—as much as 1.5 to 1.9 lbs. per head daily—when fed no grain in addition to stillage and a limited amount of hay. To increase the gains and improve the finish, a small amount of grain is often fed. No protein supplement is needed. The stillage sometimes has an unduly laxative effect. In such cases roughage should be fed that will counteract the effect, such as grass hay, straw, or cottonseed hulls.

In a Kentucky trial yearling cattle full-fed on stillage with 5 lbs. of hay a day consumed an average of 20.6 gallons, or about 175 lbs., per head daily and gained 1.55 lbs. a day.[164] Per pound of gain, 113 lbs. of stillage and 3 lbs. of hay were required. It was estimated that 13.4 lbs. of total digestible nutrients were required per pound of gain, which is considerably more than needed when cattle are fattened on a ration with a liberal amount of grain.

In a Maryland test, rye stillage containing 5 per cent dry matter satisfactorily replaced one-half the concentrates for dairy cows.[165] Thus fed, the stillage was worth 5 per cent as much per ton as the concentrate mixture. To get some of the cows to consume a large amount of stillage, it was necessary to warm it and add a little molasses.

Strained or thin stillage proved too watery for use in swine feeding in Kentucky tests.[166] Heavy feeding of distillers stillage tends to produce soft pork.

In another Kentucky test whole stillage containing 8 to 9 per cent dry matter was used satisfactorily to replace a considerable part of the corn in a growing mash for chickens.[167]

957. Yeast.—The most common kind of yeast used in stock feeding is *brewers' dried yeast,* made from the yeast filtered from beer or ale after the fermentation is completed. This yeast is of the *Saccharomyces* type. Dried yeast of the *Torula* type is now made in this country by the fermentation of the waste sulfite liquor from making paper pulp. Yeast for feeding can also be produced in the fermentation of molasses for alcohol.

The chief use of *brewers' dried yeast* in stock feeding is as a vitamin B-complex supplement, especially for poultry. It is very rich in all the B vitamins, except that it has very little vitamin B_{12}. It also supplies two of the unidentified vitamins important for poultry.

Brewers' dried yeast has an average of 44.9 per cent protein, and is high in phosphorus, containing 1.56 per cent. In drying the yeast, it is commonly heated sufficiently to kill the yeast cells and destroy the fermenting power. Otherwise, too great fermentation might be produced in the digestive tract, causing indigestion.

It is shown in Chapter VII and in the chapters of Part III that there is generally no advantage in adding yeast as a vitamin supplement to livestock rations that already supply sufficient amounts of the B-complex vitamins. (210) The use of irradiated yeast as a vitamin D supplement is discussed in Chapter VII. (203)

Yeast may sometimes have a special value to restore the appetite of animals that are badly run down. In the case of animals which are very debilitated because of heavy infection with internal parasites, treatment with an anthelmintic to remove the parasites is often fatal. Drenching the animal with a yeast suspension and then feeding yeast for a few days tends to restore the appetite and build the animal up so it can stand the treatment for removal of parasites.[168]

If the price of brewers' dried yeast or other dried yeast is such that it is an economical source of protein, it can be used in place of other protein supplements in stock feeding. In Canadian experiments brewers' dried yeast equaled linseed meal for dairy cows.[169] In Hawaiian trials dried yeast, fed as 25 to 35 per cent of the concentrate mixture for dairy cows, gave nearly as good results as soybean oil meal.[170]

Though the protein in dried yeast helps to supplement the protein of the cereal grains, dried yeast is not satisfactory as the only protein supplement for swine or poultry. It gives satisfactory results when used in combination with supplements that provide protein of better quality.[171] In English experiments dried yeast tended to produce rickets in pigs when forming 20 per cent of the ration, unless an abundance of calcium was supplied and also of vitamin D.[172]

Dried torula yeast, or wood yeast, produced from sulfite waste liquor, resembles brewers' dried yeast in composition and may be used similarly. Torula yeast is apparently lower in methionine than brewers' yeast, and should be used with feeds that supply an ample amount.[173] It also has considerable nonprotein nitrogen, which cannot be utilized by poultry or swine.[174]

Dried torula yeast satisfactorily replaced soybean oil meal as the protein supplement in New Hampshire tests with dairy cows and laying hens.[175] A combination of torula yeast and soybean oil meal was a satisfactory protein supplement for chicks, but the growth was reduced when the yeast was the only protein supplement.

958. Other fermentation by-products.—Other dried or condensed by-products are produced from the residue that remains when alcohol is made from molasses, or when molasses or grain is fermented in special processes to make acetone, butyl alcohol, and other products. These by-products are used chiefly in poultry rations as vitamin supplements to supply riboflavin and other B-complex vitamins, and also certain unidentified vitamins or factors. (221) They are sold under various trade names, with guaranteed content of riboflavin.

Yeast dried grains and *vinegar dried grains* are by-products in the manufacture of yeast and of malt vinegar from grain and other materials. They resemble rye distillers dried grains in composition.

V. Formula Feeds, or Commercial Mixed Feeds; Mineral and Vitamin Mixtures; Premixes

959. Formula feeds.—The manufacture of formula feeds (commercial mixed feeds) has become a very important industry in the United States. It is estimated that 33 million tons of formula feeds are made annually in this country, with a value of well over two billion dollars. About 6,000 feed manufacturers produce formula feeds under their own brands, and a much greater number of feed stores make mixed feeds for their customers.

About 60 per cent of the tonnage of formula feeds is made for poultry, about 19 per cent for dairy cattle, 11 per cent for swine, and smaller amounts for beef cattle and sheep, which are fed chiefly home-grown grains.[176] In the intensive dairy districts of the Northeastern and North Atlantic States by far the greater part of the concentrates fed dairy cows are formula feeds, and large-scale poultrymen use chiefly formula feeds.

Most of the formula feeds on the market are intelligently and honestly made of good ingredients, and such feeds produce very satisfactory results. In purchasing formula feeds one should consider the general reputation of the manufacturers of the various brands of feed available. He should also find from the feeding stuff inspection reports of his state whether any particular manufac-

turer has in the past been fully meeting his guarantees of composition and of declared ingredients.

In the opinion of the author there is no one best formula for a feed mixture for any class of stock, in spite of claims sometimes made to the contrary. Many formulas can be recommended that will produce excellent results, and the choice among them will depend primarily on the prices of the various individual ingredients at any particular time.

It has been emphasized in Chapter XII that it is decidedly uneconomical to adhere to the same formula, month after month and year after year, without regard to the relative cost of the various individual ingredients that are available. Feed manufacturers can obviously study the changes in the prices of various feeds much more closely than most farmers. They are therefore in a position to make such changes in their formulas as are necessary to furnish efficient mixed feeds to their customers at the minimum price.

Manufacturers of formula feeds who have chemical laboratories or who have chemical service available can control the vitamin content of such feeds as poultry mashes. This is difficult when they are made on the farm.

Suitable concentrate mixtures and complete rations are recommended in Part III and in Appendix Table VII for each class of stock. It is believed that these mixtures and rations will all produce excellent results, when made of good-quality feeds, and fed intelligently. It is hoped that these recommendations may be helpful both to farmers and to those manufacturing mixed feeds.

In deciding whether to buy a commercial mixed feed or to mix a suitable feed himself, one should base his decision on the cost of the mixed feed and the cost of the home mixture, including the labor for the mixing. Convenience must also be considered. Unless a manufactured vitamin and mineral premix is used, it is difficult to mix on the farm such complicated formulas as are now commonly used for poultry mashes, pig starters, and milk replacers for dairy calves. This is because of the very small quantities of certain vitamin and mineral supplements usually included in such formulas.

Often a high-grade mixed feed can be bought at a price little or no higher than it would cost to mix a feed of the same value on the farm. The wise manufacturer secures his profits by building up a large volume of sales through selling his feed on a narrow margin of profit. He uses his ability to purchase ingredients in large quantities and his knowledge of the prices and values of various ingredients to make mixed feeds that furnish nutrients most economically.

Especially in using molasses, the feed manufacturer has a great advantage over the individual farmer. When bought by the feed manufacturer in tank cars, molasses is often the cheapest source of carbohydrates in many parts of the country. Yet, when purchased by a farmer in barrels, molasses may be more expensive than grain.

960. Importance of keeping safely within the guarantee.—It is exceedingly important for the permanent success of any feed manufacturer that his feeds at all times conform strictly to the guarantees of chemical composition and ingredients. Only when this is done, can a reputation for uniformly high quality of product be gained.

If a feed manufacturer does not make chemical analyses at frequent intervals of the ingredients he uses and of his mixed feeds, he must fully consider the variations in the composition of the ingredients. Otherwise, the formula feeds may fall below their guarantees. To be safe, the guarantees for protein and fat must be sufficiently below the average composition, and the fiber guarantee enough above the average, so that the feeds will always meet the guarantees.

961. Lower-grade feeds.—A large proportion of the formula feeds are made of only high-grade ingredients. Others, especially some of those for cattle, contain more or less of cheaper products, such as ground grain screenings, oat hulls, and oat mill by-product (oat mill feed). These materials have a definite

feeding value and can be used best when intelligently combined in reasonable proportions with feeds of higher value. In particular, molasses adds to the palatability and usefulness of a mixture containing considerable grain screenings.

Formula feeds of this kind are sometimes economical when honestly sold for what they actually are. In purchasing such feeds one should use good judgment and not pay more than the product is really worth, as shown by the guaranteed composition and ingredients. Particular attention should be paid to the fiber guarantee. For example, high-quality formula feeds for dairy cows should have no more than 10 to 12 per cent fiber. If the fiber guarantee for the feed is over 12 per cent, it probably contains considerable of a low-grade ingredient.

962. Open formulas and closed formulas.—Most of the formula feeds are made with what are called "closed formulas." In this method the minimum percentages of protein and fat and the maximum percentage of fiber are guaranteed. Also the ingredients in the feed are usually stated on the feed tags, for this information is required under the feeding stuff laws in most states. However, the amount of each ingredient is not specified. In the "open-formula" method, which has been used chiefly by co-operative organizations of farmers in manufacturing formula feeds, the number of pounds of each ingredient in a ton of the mixture is also stated.

The open-formula method has certain advantages, but also certain disadvantages. The exact amount of each ingredient is known at a glance, and a farmer can easily compare the cost of the feed with the cost of making the same or a similar mixture on his own farm. Also, the amounts of digestible protein and of total digestible nutrients in the mixture can readily be computed, and the computations can be checked by anyone from such tables as Appendix Table I of this volume. The amounts of digestible protein and of total digestible nutrients are usually stated on the feed tag, along with the open formula. These figures are necessary, if one desires to compute a balanced ration accurately in accordance with the feeding standards.

Such data are not commonly given by manufacturers of closed-formula feeds, and, if given, the accuracy of the figures cannot be checked, because the amounts of the various ingredients are not known by the purchaser.

Unfortunately, there is no method by which the exact amount of any feeding stuff in a formula feed can be determined with accuracy. The best that can be done by a skilled microscopist is to ascertain whether any particular ingredient is present and to estimate approximately the proportion in which is occurs. The laws can be enforced that require the ingredients in a formula feed to be declared, for the microscopist can testify definitely on the witness stand that he has or has not identified any particular ingredient in the feed.

On the other hand, a law requiring that the manufacturer guarantee the amount of each ingredient in a formula feed could not be enforced. This is because the amounts of the various individual ingredients could not be determined with sufficient accuracy to serve as a basis for prosecution when the law was violated.

One of the reasons why nearly all private manufacturers of formula feeds have been unwilling to use the open-formula plan is that this might make possible unfair competition from unscrupulous competitors. Such competitors could print the same formulas on the feed tags, but cheapen the actual composition of their feeds by making changes in the proportions of various ingredients. Nevertheless, they could meet the same guarantee of ingredients and of content of protein, fat, and fiber. Therefore, they could not be prosecuted under any feeding stuff law. Such an unscrupulous manufacturer could sell his cheaper feeds at a lower price than the first concern could sell the feeds which had been made according to the published formulas. Yet, he might claim that his feeds were the very same products as those made by the honest manufacturer.

In addition, if a feed manufacturer believes that through knowledge and experience he has developed formulas that are particularly efficient, he may naturally hesitate to give this information to his competitors by using the open-formula plan.

963. Mixing feed on the farm.—Statements are sometimes made that it is difficult to mix on the farm several ingredients into a mixture that is sufficiently uniform to produce the best results in stock feeding. As a matter of fact, it is relatively simple, except in the case of a mixture made up of many ingredients, such as some poultry mashes, pig starters, or mixtures for young dairy calves.

One should first decide on the amount of each ingredient to be put in each ton or each 1,000 lbs. of the mixture, and write down this formula, so it can be followed exactly. Then a smooth, tight floor should be swept well, and the ingredients assembled. Scales should be at hand to weigh the feed, if full 100-pound sacks of each ingredient are not used.

Some of the ground grain, if it is the chief ingredient, should be spread on the floor to a depth of a few inches. Then a layer of each of the other ingredients should be distributed over the grain, and the process repeated until a long pile has been made, two or three feet deep. If only a small amount of some ingredient is used, as in the case of salt, this should be distributed evenly over the top of the pile. If a very small quantity of some mineral or vitamin supplement is to be included, this should first be well mixed with several pounds of some fine feed ingredient, before being added to the pile.

Finally, starting at one end, the feed is shoveled into a new pile of the same shape, a convenient distance from the first pile. Shoveling the mixture over three times will usually make it sufficiently uniform. Where a large amount of feed is mixed on a farm each year, it is advantageous to use one of the small feed mixers that have been developed for farm use.

964. Premixes.—To aid the smaller formula feed manufacturer or the feed dealer in making complicated mixtures, premixes are manufactured, for mixture with the ordinary feed constituents. These contain the important but very small amounts of certain vitamin supplements or trace mineral supplements needed, for example, in poultry mashes. In a premix, the vitamin and trace mineral supplements have been very thoroughly mixed with a certain amount of a carrier, which is usually one of the ordinary feed ingredients.

These are designed to supply the proper amounts of vitamins or trace minerals, or both, when the correct percentage of the premix for the particular kind of animal is included in a formula feed. If available, such a premix can be used by a farmer in making up concentrate mixtures on the farm.

965. Storage of concentrates.—If feeds contain too much moisture, they will heat and mold when stored, especially in warm weather. The rate and degree of spoilage depend on the air temperature and humidity, as well as on the percentage of water in the feed.

Heating or molding not only decreases the palatability and general nutritive value of a feed, but still more important, it seriously reduces the vitamin content, especially of carotene. As has been stated previously, the loss of carotene in a feed mixture is more rapid when the mixture contains meat scrap, tankage, dairy by-products, or certain mineral supplements. (195)

For storage without injury, ground grain must be drier than the whole grain. When molasses is included in a feed mixture, the water content may be brought up to an unsafe level, if it is already near the danger point. This is because molasses contains much more water than most other concentrates.

To be stored safely in warm weather for any long period, the percentages of water in various feeds should not exceed the following:[177] Ground corn, 13.0; whole shelled corn, 14.7; ground oats, 12.3; ground wheat, 12.0; ground sorghum grain, 13.0; wheat bran, 13.0; wheat shorts, 12.7; corn gluten meal,

11.2; cottonseed meal, expeller, 12.0; cottonseed meal, prepress solvent, 13.0; fish meal, 10.0–12.0; meat-and-bone scrap, 10.6; linseed meal, 11.0; soybean oil meal, 44 per cent protein, 13.1–14.5; soybean oil meal, 50 per cent protein, 15.5; alfalfa leaf meal, dehydrated, 15.5.

966. Antibiotic feed supplements. —The discovery in 1949 that certain antibiotics can increase the rate of growth of chicks and young pigs opened up a new development in swine and poultry feeding. Since then literally hundreds of experiments have been conducted with various antibiotics under different conditions.

The antibiotic feed supplements on the market generally supply not only an antibiotic or a mixture of antibiotics, but also vitamin B_{12}. These supplements are produced through the growth of microorganisms that synthesize the antibiotic and also B-complex vitamins.

At first such feed supplements were often called APF, or animal protein factor, supplements. Now a supplement used for its antibiotic activity is called an *antibiotic feed supplement.* A supplement supplying both an antibiotic and vitamin B_{12} is called an *antibiotic-vitamin B_{12} supplement.*

A suitable antibiotic feed supplement will generally, but not always, increase appreciably the rate of gain of pigs, of chicks, broilers, and poults, and of dairy calves during the first 2 or 3 months of age. In most such cases the antibiotic will very slightly reduce the amount of feed required per pound of gain.

The antibiotics most commonly used thus far as feed supplements are aureomycin (chlortetracycline), terramycin (oxytetracycline), penicillin (a stabilized form), and bacitracin. Certain other antibiotics are much less effective growth stimulants or have no such effect.

Several extensive reviews have been published, which summarize the results of the many experiments with antibiotic feed supplements for the various classes of farm animals.[178] Only a very brief summary can be given here of the data. Further information on antibiotic feed supplements is given in the chapters dealing with the feeding of each kind of stock.

The causes of the growth-stimulating effect of certain antibiotics are not entirely known. It is believed that an important effect is a reduction in the number of detrimental bacteria in the digestive tract, especially under insanitary conditions of housing and management.
